1. "In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved, and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced, after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and, if need be, counter-openings are made; the external wound is closed or not, according to circumstances, and dressed and suitable splints are then applied. Under such a régime the majority of cases do well. Immovable apparatus may be used after a time, windows being left in the plaster casing to allow wounds to be dressed."—(Rose and Carless's *Manual of Surgery.*)

2. Hip Joint Disease: *Symptoms of first stage:* Night cries, lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling and deformity (either real or apparent).

*Symptoms of second stage:* Abduction; limping; pain, which is worse at night; apparent lengthening of the limb; abscess; atrophy of thigh muscles; flexion of thigh; effusion into hip joint; and there may be crepitation in the joint.

*Symptoms of third stage:* Flexion, abduction, and shortening of the limb; the joint may be dislocated or ankylosed, or suppuration may occur.

*"Treatment:* In the early stages the patient must be kept in bed, with a weight extension applied in the line which the thigh takes, and as the flexion disappears, the pulley is lowered. When the pain has disappeared and the limb is horizontal, the patient can get about with a Thomas's hip-splint, a patten on the sound leg, and a pair of crutches. These must be worn for at least six months after symptoms have disappeared. The general health must be attended to by good feeding, sunshine, and fresh air. Phelps' box is a useful apparatus in this stage. If abscesses form, they should be opened, scraped out with a flushing spoon, and stitched up. Excision of the head of the femur and free scraping out of the joint by the anterior incision is sometimes done in the early stage; but much shortening and a weak, movable joint are the results, while complete removal of all the diseased tissues is difficult. However, excision should be done where the disease progresses in spite of treatment, and where the disease is primarily acetabular. In the *late stages*, where septic sinuses are present, the head of the femur should be excised by the posterior incision, diseased bone removed from the acetabulum, and the tuberculous synovial membrane completely dissected away. Amputation is required if the disease still progresses, if amyloid disease has commenced, or if the patient's general health is too low to stand a prolonged operation."—*(Aids to Surgery.)*

3. Partial thyroidectomy, sympathectomy, and ligature of both superior and one inferior thyroid arteries.

4. *Enlarged inguinal glands* are not reducible, do not have an impulse on coughing, are tender to the touch, are not translucent.

*Hernia* may be reducible, gives an impulse on coughing, is not translucent.

*Hydrocele* is not reducible, gives no impulse on coughing, is translucent.

5. *Epithelioma of the lower lip* generally begins as a fissure, which becomes indurated, then ulcerates and extends; sometimes it is nodulated or looks like a wart. The submaxillary and submental glands become enlarged and hard. Diagnosis may be made certain by microscopical examination of a small piece removed for the purpose. Treatment consists in thorough removal of a wedge-shaped piece with at least half an inch margin. The glands should also be removed from both sides.

6. The *symptoms of acute osteomyelitis* are: Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicemia or pyemia, may be present.

7. *Posterior gastroentcrostomy.* "The abdomen is opened by a vertical incision to the right of the middle line above the umbilicus. The stomach, transverse colon, and omentum are drawn out of the wound and turned upwards, and an opening is made in the mesocolon near its root, so as to expose the posterior surface of the stomach; a portion of stomach at the lowest part of the greater curvature is selected for the anastomosis. The upper part of the jejunum is then found by passing the fingers along the under surface of the mesocolon immediately to the left of the spine, and the highest available portion of it brought into contact with the stomach in such a way that the loop of bowel selected runs from right to left (Mayo). An anastomosis is then made between the stomach and jejunum, an ellipse of mucous membrane being excised from each viscus. The edges of the opening in the mesocolon are then stitched over the line of junction, so as to bury it and prevent any hernial protrusion through the gap. After being cleansed, the viscera are replaced in the abdomen, and the wound in the parietes closed. When the patient has recovered from the anesthetic he is propped up in bed with pillows." (Thomson and Miles' *Surgery.*)

The operation is chiefly performed for cancer of the pylorus, stenosis of the pylorus (non-cancerous), and ulcer of stomach.

8. Tuberculous Kidney. "The *Symptoms* at first consist of aching pain in the loin and frequent micturition, not improved by rest. Hematuria comes on early without apparent cause, is not increased by movement or improved by rest. Pus is usually present in acid urine, and the *Bacillus tuberculosis* may in some cases be detected. In the late stages the kidneys may be felt much enlarged.

"The *Diagnosis* is doubtful in the early stages, unless bacilli can be demonstrated by the microscope or inoculation of a guinea-pig. The hematuria is much slighter than in cases of renal calculus, and is not influenced by rest. The hematuria is not so profuse as in cases of new growth. Slight attacks of renal colic may occur from the passage of caseous matter, but not severe attacks like those due to calculus. An

exploratory incision settles the diagnosis in doubtful cases.

"*Treatment.*—If on exposure of the kidney a limited portion is found to be diseased, a wedge-shaped portion is excised. If, as is more usual, the kidney is extensively affected, two methods may be adopted: 1. If the other kidney is healthy, nephrectomy with removal of as much of the ureter as possible is done. 2. Nephrotomy, followed by drainage, is done when the patient's condition is too bad to stand the bigger operation, or when the other kidney is also affected."—*(Aids to Surgery.)*

9. DEPRESSED FRACTURE OF THE SKULL. *Symptoms:* If there is a wound, the fracture and depression may be seen, and blood, cerebrospinal fluid, or brain, may be escaping. If there is no wound a careful examination is necessary, as a hematoma may form and obscure the depression. In cases of doubt an incision should be made.

In a *simple depressed fracture* there is usually some concussion, which is followed by compression from hemorrhage in the neighborhood. The depressed bone also causes compression later by the *spreading edema* it sets up in the brain. Death may result quickly, or the patient may recover and then become the subject of traumatic epilepsy from irritation of the cortex. If the depression is over the motor area convulsions or paralysis are quickly induced.

In a *compound depressed fracture* the blood escapes and does not produce compression. Concussion may or may not be present. The advent of sepsis produces inflammation of the bone, membranes, and brain, which may be limited if the drainage is free; but if not death soon follows from compression by the inflammatory exudation. During the stage of compression a hernia cerebri is formed. If the depressed fragments are early removed and asepsis is maintained the patient has a good chance, unless the brain itself is severely injured.

*Treatment.*—In all cases, except the saucer-like depressions which occur in young infants, it is necessary to elevate or remove the depressed fragments, stop all bleeding, and disinfect the wound. Symptoms should never be waited for, because, although the patient may recover without operation, the depressed bone may cause traumatic epilepsy or insanity. The skin is shaved and purified, and a large flap is turned down to expose the fractured area, or if a wound is present it is enlarged. Comminuted fragments are removed, and sharp edges which press on the dura mater are clipped away with Hoffman's forceps. If an elevator cannot be introduced under the depressed bone a trephine hole is made through the nearest sound bone, the elevator introduced, and the bone prised up. The piece of bone removed with the trephine should be replaced. If the dura mater is torn it should be stitched up and then the scalp flap is sutured without a drain, unless oozing is still going on. If the fracture has been compound it is better to drain it for twenty-four hours. In punctured fractures the hole must be enlarged by trephining, so as to remove the depressed spicules. After operation the patient must be kept quiet in a darkened room on liquid diet for a few days. *—(Aids to Surgery.)*

10. *Colles' fracture* is a fracture of the lower end of the radius; it is generally transverse, and is usually within an inch or an inch and a half of the articular surface. There is a characteristic deformity caused by the lower fragment, and the carpus forming a prominence on the dorsal surface; at the same time there is a projection on the palmar surface just above the wrist, caused by the upper fragment. The hand is abducted and pronated, and the styloid process of the ulna becomes very prominent. It is generally caused by a fall on the outstretched palm. *Treatment:* Disimpaction and reduction are effected by grasping the hand by the "shaking hand" grip, extending and adducting the hand and lower fragment. Put on a splint. Massage and passive movement must be started by the end of the first week.

1. HYGIENE.

| | EXPIRED AIR. | INSPIRED AIR. |
|---|---|---|
| Oxygen..... | 16.6 per cent. | 21 per cent. |
| Nitrogen..... | 79 per cent. | 79 per cent. |
| Carbon dioxide... | 4.4 per cent. | 0.04 per cent. |
| Other gases..... | Often present. | Rare. |

2. *Bacterial diseases in which the respiratory tract is the portal of entrance:*—Tuberculosis, pneumonia, diphtheria, influenza, scarlet fever, small-pox, whooping-cough, chicken-pox, measles.

3. *Advantages of Pasteurization of Milk:*—"(1) That most if not all of the common bacteria and their toxins are killed. (2) That the ordinary ferments and germicidal properties of the milk are not destroyed. (3) That the process may be accomplished on a large scale, and furnish a commercially safe milk. (4) That the taste, appearance, odor, and cream-separation quality of the milk are not altered. (5) That pasteurized milk, if kept cold, furnishes a clean, healthy milk, safe for infant food and other uses."—(Price's *Epitome of Hygiene.*)

4. The specific gravity of cow's milk, at 60° F, is about 1029 to 1032. It depends on the amount and character of the solids present in the milk.

5. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

*Natural immunity* is this power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

*Acquired immunity* is this resistance acquired: (1) By a previous attack of the disease caused by the bacteria, or (2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are: (1) A previous attack of the disease; (2) inoculation with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

"*Active acquired immunity* is produced by the action of living germs or their toxins introduced into the animal.

"*Passive acquired immunity* is obtained by a direct transference of an immunizing substance from an immune animal to a susceptible one. Active immunity takes some time to develop, but, as a rule, lasts longer than passive immunity, which is immediately established."

6. *Sunlight* is a disinfectant if the direct rays of the sun are allowed to fall on the (non-spore bearing microorganisms) for at least half an hour.

Dry heat, at boiling point, is a good disinfectant. Moist heat is better, because it has more penetrating power. Steam, under pressure, is better still. Fire is the best of all disinfectants, but its application is not always practicable.

7. "The animal in which a parasite undergoes its sexual life is called the definitive or final host, that in which it passes its larval existence the intermediary host. For example: Man is the intermediary host of the malarial parasite, the mosquito the definitive host. A single animal may, however, be both definitive and intermediary host; thus Trichinella may pass its larval existence in the muscles of man and its sexual life in his intestines."—(Stitt's *Bacteriology*, etc.)

8. *Prophylaxis of bubonic plague:* "Vermin, particularly rats and mice, are susceptible to plague; indeed, the former are believed to be the principal carriers of it. They infect the ground, dwellings, foods, and water. Therefore, safety lies in the destruction of all vermin in the houses. As dogs and cattle are also susceptible to the disease, they should be carefully protected from exposure. Screen dwelling and rooms; since the ground becomes infected by rats, and infected excreta, and because wounds of the feet and legs are frequent portals of entry for the specific bacillus, the constant wearing of shoes is a wise prophylactic." (Langfield's *Infectious Diseases.*)

9. A *diphtheria carrier* is a person in whose body the bacilli of diphtheria can be found, although the person does not, at the time, give any symptoms of the disease.

Persons in whose mouth or throat or nasal secretion the specific bacilli are found should be isolated until constant examination is negative for two weeks.

10. "In *the combined system of sewerage* the rainwater is disposed through the same pipes through which the sewage passes. This system necessitates pipes of larger caliber, in order to take care of the occasional large quantities of storm water, which water serves also to give the sewer pipes a thorough flushing. On the other hand, the large caliber sewer pipes of the combined system cause a very sluggish flow of sewage in them in ordinary times, with consequent adherence of sewage to the sides and a decomposition of sewage and creation of foul gases. The utilization of

the sewage is also more difficult in the combined system because of the large dilution of the sewage and the expense of separating the solid excreta from the fluid.

"In *the separate system of sewage* the rainwater is removed separately through a distinct system of pipes taking care of the rainwater only, and this water may safely be disposed of into rivers and nearby watercourses without special danger of contamination with sewage matter, as in the combined system. For smaller cities, with modern sewage-treatment plants, the separate system of drainage is preferable, and, although it requires a double system of pipes, etc., is cheaper in the end, and less objectionable in many respects."—(Price's *Essential of Hygiene.*)

## Miscellany.

**Medicine and the Law.**—W. Sampson Handley mentions among distinguished lawyers recruited from the ranks of medicine the Right Hon. Sir Robert Finlay, Member of Parliament for Edinburgh and St. Andrews Universities, and a former Lord Rector of his own University of Edinburgh. The son of an Edinburgh physician, he graduated in medicine at Edinburgh, and was then called to the Bar. His brilliant subsequent career as Solicitor and Attorney-General proves, at any rate, that a medical education offers no insuperable obstacle to subsequent legal success.—*Lancet.*

**First Aid in Aviation.**—At the recent International Congress on First Aid and Ambulance Work, held in Vienna, the subject of aeronautics and aviation received considerable attention. Hinterstoisser, of the Army Aeronauts, stated that first of all smoking near an airship or aeroplane was distinctly criminal. Nobody should rush to the place where any air craft was preparing to descend. Medical attendance should be obtainable within an easy distance of an aerodome, and a portable first-aid outfit should be ready at hand, as well as fire-extinguishing apparatus. Persons with an unstable circulatory or respiratory system should not meddle with areonautics, and perfect hearing was also necessary for a would-be airman.—*Lancet.*

**The Smallest Essential Part of the Automobile.**—The smallest part of an automobile that is absolutely essential to normal action is the rubber washer on the core of the tire valve. It weighs only one eighteen-hundredth of an ounce. One cent will pay for enough washers of this kind to equip ten automobiles, yet, when lost, it is one of the most difficult pieces to replace on the whole car. Fine thread soaked in rubber cement and wrapped around the valve core at just the right amount will provide a temporary repair.—*Motor.*

**A Learned Consultant.**—"Speaking of doctors that one has met in consultation," said Dr. Monroe, "puts me in mind of one that I met some years ago. It was a case of myalgia. This man examined the heart exhaustively, and in talking it over, said, 'Doctor, I think your patient is in the gravest danger.' I asked 'How do you come to that conclusion?' 'Well,' he said, 'I can hear the first and second sounds of the heart but fail to find the third sound!' A little later I happened to speak about there being sufficient compensation. 'Oh,' he said, 'they are good pay!'"—W. T. Bertrand, in "Stories of Doctors, etc."

**Warming the Carbureter.**—A 2-quart rubber hot-water bag filled with boiling hot water and placed close to the carbureter will warm it up so that starting will be facilitated.—*Motor.*

**To Stop an Oil Leak.**—A leaking transmission case may often be made to hold the oil by adding graphite to the lubricating oil. The graphite settles and plugs up the openings.—*Motor.*

**Agnosticism in Medicine.**—The contemplation of advanced cases in the medical wards of a hospital is apt to breed a spirit of agnosticism and hopelessness with regard to the capacity of medicine to relieve disease—the attitude of mind which treats a majority of cases with rest in bed and compound tincture of cardamoms. But on the firing line of the medical army, where the general practitioner spends his days and nights, such a spirit is impossible or leads to disaster to patient and practitioner alike.—*British Medical Journal.*

### REMARKS UPON MENTAL INFANTILISM IN THE TIC NEUROSIS.*

BY L. PIERCE CLARK, M.D.,

NEW YORK.

IN my first study[1] upon mental torticollis as a form of psychoneurosis of the obsessive type, I undertook to show that certain types of tic such as mental torticollis were but continuations of habit movements. The tics remain as fragments of the complete habit and persist as crude symbols, which serve as a most intimate and deep need of the abnormal personality of the individual patient. By the analysis of an illustrative case in that paper the habit movement was traced back to earliest infantile life and found there to have been closely interwoven with the mother complex initiated by a caressing, petting act of affection by the mother. It was also shown that the mother's part of the neurosis but served to waken and fasten upon the child an autopleasurable act, which act or habit movement took on secondary autoerogenous satisfaction in later life. The act, continued and modified in later life, constituted the tic from which the patient finally sought relief. It further developed that the main reason for the habit movement and its tic successor, being irrevocably attached to the patient, was due to the inherent sense of inadequacy of feeling and will generated from the conflict of doubt, the latter conditioned upon the most primal antagonism of the hate instinct in its process of sublimation by the love instinct. The whole chain of events served to form the vacillating, indecisive character and will of the obsessive neurotic of which the torticollis was but one of the group characters in the incompletely evolved neurotic. In the second paper[2] I called attention to a second type which was termed acute mental torticollis from a breaking through of a sexual repression, the tic movement being a physical counterpart, a conversion of a hysteric complex rather than a substitution, as in the pure obsessive neuroses. The case reported in detail in the second paper possessed many features common to both types of makeup and might, therefore, be called a form of mixed neuroses, it having many attributes common to both constitutions.

In both papers the cases reported had much in common in their mental infantilism which was shown in both in adolescence and in later life. They both showed an incompletely sublimated hate instinct. They never established real friendly relations with a large group of other children; could not get *en rapport* with their social environment; had inconclusive love affairs; both were unmarried and had inadequacy of feeling and will, and lived in a vague world of doubt, indecision, and vascillation. In short, they both met on the common ground of all mental torticollitics in possessing, each in his individual way, what is termed mental infantilism.

The purpose of this third paper is to elucidate some of the main features of this mental infantilism in its broader aspects, as illustrated in an exquisite case of multiple tics. I have taken a rather ideal youthful ticeur for the pattern in order to work out the genetic values of the several characteristics of infantile life. Just as one not infrequently makes clear the underlying anatomic pathology of a rare or obscure disorder upon the maximum clinical expression of that disease—as shown, for instance, in the many studies of epilepsy that are based upon its severest manifestations—that of status epilepticus—so I have chosen this particular case for the purpose of showing a large canvass of tic disease to point out many of the salient and glaring faults in the mental makeup. It will be found a paradigm of mental infantilism, and in which there will be seen, no doubt, many characteristics but little emphasized in many another ticeur, or altogether wanting in some. In the main, however, the clinical study will serve its illustrative purpose the better, inasmuch as I propose not to detail at any great length the various mental characteristics of such individuals, for that has been thoroughly and effectively done by a host of writers before; but I hope to show how one may resolve all the successive patterns of tics into the first one great tic, and then see what may be made of its real genetic value. Thus in some measure I hope to make plain what may be considered our fundamental manner of approach to the ticeurs and their mental characteristics. I assume all will admit that to understand the real motive of the tic disorder is of little use if one fails to inaugurate either an improved system of treatment of it or at least take proper precautions to prevent its future occurrence, either by inculcating better systems of home and nursery training, or, if that be ineffectual, to teach society that such family stock should be restricted in marriage. The latter view will not be so utopian as it may seem if physicians will endeavor in future to bring to public notice exact, definite and concrete facts upon which they base their radical opinions. However, before we go so far as conjuring eugenics to our aid, it is wise for us to make every effort to inculcate better nursery education and see to what extent the primary physical and mental habits are modifiable and which ones are really benign, as it were, and may safely be left to correct themselves in adolescent growth. In order that our case study may have a proper setting foundation, we may with advantage hastily sketch some of the salient characteristics of mental infantilism as seen in ticeurs and in some meas-

*Read before the Section on Medicine, New York Academy of Medicine, January 20, 1914.

ure weigh the essential import they bear to the primary instincts.

The outlines of mental infantilism as first laid down by Charcot leaves but little to be desired as to description. His statement that the tics are physical manifestations of a psychical disorder certainly proves that as a fundamental postulate it is the surest and sanest view of the disease in modern medicine. In the further development of this idea, the French school headed by Brissaud has been most active. When we fully grasp the application of the above fact one begins to understand in some measure why voluntary and rational acts *may* become involuntary and irrational. It also gives us some hint why the inhibition of a confirmed tic is so difficult and laborious. The presence of a uniformly weakened will in the ticeur makes the extra power of inhibition of the will doubly impossible; nor is the will alone at fault; there are other peculiar eccentricities of behavior that indicate a greater or less degree of mental instability in other fields than that of the domain of will solely. This defect in will is the more difficult to describe as individual patterns differ in many respects as widely as the individual kinds of tics themselves. We may say, therefore, that mental infantilism is a polymorphic defect of the psyche. If one takes but a single particular characteristic from the ticeur's psychic makeup, one may nearly as easily find its counterpart or similitude in another not so diseased or even in a so-called sound individual. It is the *tout ensemble* that forms the true picture. Appearances in no other clinical field of the neuroses are more deceptive as to the real constitution of the inner life of the individual than in the ticeur. Many times the brilliance of mind, the genius type of ticeur, may mask his failings. His intelligence may be of a superior order, his imagination very fertile, his mind apt, alert, and original. Only painstaking analysis will remove the obvious blind to characteristics that may be hidden, but are none the less real.

A careful analysis shows the ticeur's mental defect is not so much evidenced in mental insufficiency as in an inequality of mental development. The surprising fact brought out in the analyses, even of many ticeurs of brilliant minds, is the embryonic condition of one or the other of their mental faculties. In short, these disharmonic processes of mind consist either in absence, arrest or delay, or perversion of mental growth, and, what is more pertinent, these contrary processes may coexist in the same individual. We must remember that most of these mental imperfections of mental balance are *normal* in children and in a great measure are only overcome in adolescence. In the normal infant the beginnings of mind are characterized by irregular implantation of new instincts, yet their memory associations become regular and stable as will and the higher mental functions are developed. But the ticeur's childhood is vascillating and volatile. One of my patients stated when he associated first in boyish sports he carried a stone near at hand in his left pocket. His first approach to his comrades was with mingled feelings of hate and friendship, peace and war, and he didn't care much which one should dominate. Such an attitude shows an active conflict of the love and hate instincts. The ambivalency of the emotions of the ticeurs are shown in that timidity and rashness, artlessness and obstinacy which may be present in apparent contradistinction side by side in any personality study. They laugh and cry at the same thing on different occasions. Their loves and hates are unbounded, and are many times projected alike toward the same individuals. In fine, it is greatly in the emotional field one sees the larger discrepancies of character of the ticeur which makes for a character-defect. These facts are the more glaring by comparing the individual ticeur with healthy subjects of his own age. Nor is this mental infantilism of the ticeur a mere matter of lack of disciplinary training and education during childhood, as ordinarily understood, though it is frequently increased by a misdirected teaching. The example precept of the parents and older children of the family teaches the truth of the naïve diction of Freud, that one should know there are shorter and perhaps more potent roads for the transmission of neurotic symptoms from the parents than through heredity. The point is made the more obvious when example and heredity work in unison, as they so often do in the formation of the ticeur's character and disposition. If pampering and petting are bad for normal children it is doubly ruinous for the potential ticeur in childhood where absence of restraint, negligence and weakness are allowed to develop into the adult infirmities of later life. Such individuals form the "big children," the badly bred and capricious, incapable of self control, as shown in one of Meige's cases;[1] a young man of 19 years, intelligent, educated, ready to graduate were it not for the interruptions his studies had undergone, and to all appearances he had arrived at manhood's estate. None the less, he presented the mental condition of a ten-year-old boy. He was fickle, pusillanimous, naïve and emotional; he laughed at trifles and was provoked to tears at the first harsh word; his nature was restless, his mind inconsequential; he was by turns elated or depressed for the most trivial reasons. Notwithstanding his seventy-one inches in height he was still fed, dressed and put to bed by his mother. In spite of his nineteen years, this young man still had a eunuch's voice and a minimum of axillary and pubic hair—in fact, one might say that physically he was nineteen years old and mentally ten.

Though *mental* infantilism is the distinguishing makeup, it is not without physical counterparts, as shown in the above case, and is commonly enough met with in any large clinical experience.

While it is unprofitable for us to linger too long on the more or less well-known manifestations of instability of the will in the ticeur, the contrast to normal volition is striking to any one caring to make the comparison. We shall now make further analysis of the genesis of the insufficiency of will, the irresolutions of the ticeurs. Many classic descriptions of the ticeur's character in acquiring knowledge are shown in even such simple mental processes as learning to read. The potential ticeur fails in this task, which is at once intellectual and absolutely familiar to most normal children. Read many such children cannot, and though they attempt to concentrate the attention, the will cannot hold the attention, the eye jumps erratically from line to line, and his many trials not infrequently end in his throwing the book aside, or, he is able to read only in a sing-song or childishly monotonous manner. One sees a severe arraignment of the incomplete repression of the sadistic (hate) impulse in one of Charcot's patients, who, whenever he saw a razor or a knife, began to thrill

and feel afraid. He imagined he was going to kill some one, or that some one was going to kill him. He had the same sensation when he saw a gun, or even if the notion of a gun came into his mind. The mere thought of it agonized him. The fancy of murdering some one struck him, and up to a certain point he was desirous of fulfilling the desire. Often he was conscious of an irresistible longing to fight somebody.'

It will be seen that this case is an excellent illustration of an incomplete sublimation of the hate instinct, giving rise to illusory ideas of its sadistic satisfaction. The very symbols of the instruments by which the aggressive assaults were to be made are characteristic. It is in such that infantile moods are fertile soil for the development of tics or habit movements. It has been aptly said, as these neurotic children think, so do they tic. In the majority of ticeurs, as will be shown in my case later, the pent up and unsatisfied libido overflows in a whole series of habit movements. Not infrequently a single case may show fully developed tics, habit movements and general physical and mental restlessness, which latter phenomena have not yet budded into the fruit symptoms of habits; they are veritable citrus trees of developing motor disorders, whose fruitings range all the way from buds of movements to those of the fully ripened fruit of pronounced tics. Furthermore, as mentioned before in preceding papers, the ticeur even when fully developed is but a half-way stage to a fully developed obsessive individual with fixed ideas, phobias, and various types of obsessive thinking. Not infrequently the ticeur has but a part of his real disorder expressed in an outward physical expression of the deep lying roots of the full mental disorder of obsession. Should an obsessive idea entail a motor reaction, it gives rise to a tic as stubborn of removal as the idea itself, and *vice versa*. They may also go in pairs, or even multiple of the same, if the psychomotor mechanism is complex, deep, and broad. One therefore sees the irrevocable association of the two disorders, the one, the idea defect, serving as an obverse of the physical picture of tic or coextensive with it. The obsessive thinking or the nucleus of it is probably the primary mental departure in the ticeur's thought, though it may be late in its gross and outward manifestations, as in my second ticeur, who, it will be remembered, had fear of fire, death and world-wide conflagration that showed at three years of age.

It may be urged that even in veritable obsessive individuals, those engaged in true obsessive thinking, there is no direct or obvious connection between such a patient's obsessions and his tics. This observation in some cases is quite true, but when the two disorders—the one a motor symptom and the other a pure psychic disorder—are traced to their genetic origin, one always sees there an intimate and common stock fund of energy from which both proceed. The second case study shows this in spite of the fact that Miss C. was not a true unmixed obsessive type. She could not make a broad and friendly contact with others; she regressed into infantile musings on sexuality and the meaning and end of life. The increased and pent up libido was then displaced into fire obsession and death. The same feelings being balked in the father attachment developed into an apoplexy phantasie at his death, and the tic resulted at the next great turn in the road of sexual compensation. The consciousness of guilt also played no small part in the motor transference from the psychical sphere. It is by no means a radically new idea that the ticeur has the characteristics of the obsessive individual nor that their common fault is an inadequacy of will which is generated by doubt. One may easily verify these facts in an endless evidence of clinical experiences from the literature of both tics and obsessive thinkers; but that the doubt mania physically and psychically expressed in both is due to the primary warring instincts of hate and love is new to the theory of tics. Thanks to Freud, all the foregoing theories are, however, made plain. But one may ask, why do not all children possessing mental infantilism who have a warring conflict in the hate and love instinct become ticeurs or obsessive individuals? Such children with benign conflicts, it may be answered, do not have a strong parental fixation as exists in every ticeur—I venture to say, without exception. If one pursues the point of inquiry but a step further we may answer only in uncertain and indefinite terms, that the irrevocable parental fixation is probably conditioned upon organic and structural grounds, and at this point our subject must rest for further observation and study.*

To those given a keen, critical faculty, it may seem that even now, though we accept this theory, a full and final explanation of the tics is not at hand, and that the future holds much for the real

*It may not be out of place at this point to state briefly Freud's theory for the obsessional neuroses, inasmuch as much of it is quite new and many readers may not be familiar with its essential tenets: The affect of the painful idea does not become transformed into physical symptoms, as in the *conversion* mechanism of hysteria, but affixes itself to other ideas not in themselves unbearable, thus producing by this false relationship a *substitutive* symptom, an obsession.

The full explanation of the mental technique by which this state of substitution is brought about may be reviewed at length in Hitschmann's "Freud's Theories of the Neuroses" (translated by C. R. Payne); much curtailed, the principle may be stated as follows: In all such obsessive neurotics the *transformed* reproaches which have escaped repressions are always connected with some pleasurably accomplished sexual act of childhood but may be enormously distorted and displaced so its sexual character may be almost entirely lost. The obsessive acts really represent the conflict between impulses of opposite instincts, love and hate, which are usually of equal value. The warring conflict engendered makes for a curiosity to discover the meaning of life forces (sexual largely) and the desire to know the end thereof. The nuclear-complex of all this is a precociousness of emotional life and an intensive fixation on one or the other parent or brother or sister. The intensive love fixation waxes the stronger as the unconscious hate requires increased barriers against its breaking through into the main or everyday personality. As a result of these conflicts the will is partially weakened, there is an incapacity for resolution, first in the realm of love alone; then later succeeds a diffusion or displacement of the mechanism all over the field of action. A series of secondary defense mechanisms or helps are now brought in and these may enable the obsessive person to get square in a limited way (as religious practices enable many to do). Some special adaptation is required sooner or later, and the individual, having used up all the helps, then falls back upon different forms of obsessive acts and thinking. Thus the obsessive neurosis is generated.

If one is not permitted to draw deductions from a few data as to the further genesis of the tic disorders, we may still hold out a tentative hypothesis pieced together from many sources that a certain type of nervous makeup is inherited. In such the emotional life is precocious much beyond the intellectual faculties. The ticeur in infancy has the emotional feelings of love and hate of an adult. Their very precociousness aids the parental fixation and adhesion, and makes it the more difficult for the libido to detach itself at the proper age. One should bear in mind that the parental fixation in itself does not directly produce the mishaps of adult life, but this small fault in infancy generates wider and wider maladaptations as development progresses. It is these latter glaring faults and trends that make for the character defects, and these readily break down the final effort at adaptations and adjustments producing the tic or obsessive disorder. But the essential nucleus of the defect is the lack of balance, precocious parental fixation, and continued attachment to the parent-stem, that makes the adult defect possible. The very infantile precociousness of the emotions argues for the hereditary transmission of destructive temperamental qualities. Here, as elsewhere in tracing hereditariness in the so-called functional nervosities, one should take as the unit character for study the *mental traits* or *trends* and exclude definite disease entities applied to ancestral disorders. I believe it is not too suppositious to think that many of these variant types of obsessive individuals are really atavistic in makeup and have continued on from one generation to another special defective traits of emotional makeup which are fortunately denied the average individual.

solution. The fact, however, must not be lost sight of that if opinion of the cure of the tics in the past has been so nihilistic, it has been due to the fact that the sufferers have not been approached on the right grounds and that when we do this we shall find the character material more plastic and amenable to sincere treatment. The rapid change for the better in the ticeurs shown by this treatment indicates its superior value over older methods. It is too early to speak of end results.

To retrace our steps a bit to the main theme in the elucidation of the fundamentals of mental infantilism, one sees the very sexual attachments to the parent are necessarily most infantile. Such children cannot be expected to make a normal adolescence when so primitively tethered to the parent stock and its adhesive pull against the child's advance into the normal sexuality of adolescence and adult life must be great indeed. One may rightly count that this fact alone may account for a great deal of the irregularities, the strange insufficiencies of the mental characteristics in the ticeur. This is precisely what one finds on closer analysis, that the maximum of mental faults concern the emotional sphere of the mind, and that, too, concerned or flowing out of the sexual instincts. This is remarkably demonstrated in one of my obsessive patients, a woman of 56 years of age, now married for twenty-five years, in whom the obsession of fear of death and the non-existence of life after death was finally traced to an intensive maternal fixation, which in later life resulted in an unhappy non-sexual marriage. She gained no essential peace of mind and satisfaction in life after the obsessive thinking afflicted her soon after marriage until she returned to her infantile pursuits of caring for dogs and cats, whose promiscuous sexuality and productiveness generates no obsessive thinking as her mother initiated the custom of keeping such animals in the patient's earliest infancy. In this connection it is interesting to note that my first case, after he had to some degree recovered from his tic, could walk about his old family home, indoors, on the porch, or even up and down the sidewalk in front of the house, but could not walk toward the railroad station without bringing back some remnants of his tic. The maternal attachment to the home was still so strong.

It is ironically interesting to note that a discrepancy in mental infantilism would appear to be paramount in ticeurs, in that they often show an exaggerated love of order and system, although their mental disarray is often extreme. One rarely sees this characteristic, however, in the earliest life of the ticeur; it is a defense mechanism of later life which goes to make up the grand mentality of the obsessive tic individuals. Case I. never dressed with such care as after his tic broke out; when he did not shave daily he took particular pains to overcorrect his neglect by wearing spotless linen on these days. It is also an emblem of purity, and much affected by those with irregular sexual lives who suffer from consciousness of guilt. The same interpretation, a defense mechanism, holds good for the precision of manner and conversation the ticeurs affect. In describing the symptoms of their various maladies, ticeurs rarely have a single line of bodily or mental complaints; they keep a slack line on many symptom-groups so that they can easily let go of several if the physician requires onerous tasks to correct the main cause of the personality-defect, and thus try to convince him of their betterment. Fortunately the ticeur as yet rarely realizes the importance and dominant power of the unconscious in his disease. In such one may at least fully elucidate the *raison d'être* of their sexual life without much resistance being encountered; only when the chain of cause and effect is connected up is the often silly and puerile character of infantile behavior brought out. It is probably easier to reveal the genesis of the physiomental symptoms in which a *substitution* mechanism is the case, as in the tics, than when the issue is a *conversion* mechanism, as in the physical symptoms of a hysteric complex. I believe what is made up in ease of analysis is fully compensated for by the difficulty of eliminating the tic, and, what is more important, the difficult alteration of the personality-defect based, as it is, upon the most primitive infantile sexual life and instincts.

Before closing these remarks upon some of the more essential characteristics of the mental infantilism of the ticeur, I shall attempt to summarize our theory for the mental infantilism and its particular tic disorder.

The ticeur has a strong sexual parental attachment; this is so strong that the love instinct ineffectually sublimates the hate instinct and in the warring conflict doubt and physical and psychic inadequacy arise. This situation continues and generates mental and physical infantilism, which in turn make for increased feelings of tension. Motor and psychic restlessness succeed. The motor expression manifests itself most often in habit movements of disguised sexual significance (autoerogenous pleasures), a form of physical stereotype, in its broadest psychophysical meaning. The mental state often *pari passu* takes up obsessive thinking and various physical acts and thoughts are formed as defense mechanisms, born of conscious guilt. The motor habits are usually inhibited or displaced in part, and the tic remains as a motor symbol, usually in itself nonsexual, as a fragment of the former complete habit movement. The mechanism of the completely evolved tic is either a *conversion* (hysteric) or *substitution* (obsessive) mechanism, or both.

In presenting this third illustrative case of mental infantilism, in which the habit movements, tics, panics and obsessive thinking are exquisitely shown as morbid trends in such a setting, I have purposely omitted the stages of the physical development and the neurological examination so that our attention may not be distracted by unimportant details of the patient's life and family history. I shall ask you to consider that these factors, although not mentioned, have been gone into thoroughly to make quite sure we are dealing here with the ordinary, though marked and pronounced, tic disorder.

A. C., a young man of 19, was referred to me by Dr. Walter A. Bastedo as afflicted with obsessive ideas and multiple tics, which disorders had so progressed during the past two years that his relatives had despaired of his ever recovering from them and desired his admission to some institution for custodial care. The father, who died at 53 years of age, when the boy was 11 years old, was a robust, apparently normal individual, being a foreman in a large New England factory; he never suffered from any mental peculiarity of manner or conduct. He was twice married, and by the first wife he had five children—three girls and two boys; all normal, healthy, and still living. Our patient is the only child of the second marriage; his mother has dypsomania, which really developed before her marriage with the patient's father. Aside from this defect, which several members of the mother's own

family also possessed, in consequence of which, or at least following her alcoholic habits she had a lessened sense of responsibility regarding the welfare of our patient whom she never cared for, the history was negative. A half-brother and sister have looked after our patient since the father's death, eight years ago. The personal history as regards the physical development of our patient was entirely negative. On the other hand the mental growth was peculiar. His older half-sister states that he never seemed "just right" from birth. He never grasped things as other boys did. He was very defective in learning some things and was very bright in others. He was very good in spelling, literature, English and history, but very poor in mathematics. His nervousness and oddities of manner and conduct steadily grew on him in spite of a persistent schooling and good associations. The peculiarities of manner and conduct may be seen to greater advantage in the following personality study which was obtained from the patient and his older half-sister, and is therefore a composite summary of their united assistance at several examinations.

*Personality Study.*—The young man is now about two years backward in normal education for one of his age. He has good powers of observation and is able to describe accurately what he sees or hears. He has always been deliberate in his judgment, slow in making up his mind, and has always been afflicted with a sense of inadequacy and doubt as to his ability. He has always been imaginative in fanciful day dreaming, but has little constructive imagination. For instance, several years ago he wrote a book on what he should like to do with his life, but while the things he set down to do were rationally possible for a clever, resourceful man, they were for the most part entirely beyond the patient's ability of attainment. Among other things he was to conduct a large realty concern in the city, and he was to be the general manager of it all. Again, he planned to be a builder or architect, to lay out whole cities, etc.; the patient being possessed of a slight ability to draw, this no doubt provoked some of these fancies. He plans ahead in an equally fantastic manner, but seems never to have been able to mold circumstances to win any of his goals. Even in a small way, among home surroundings and with boyish associates, he was never able to handle unusual situations, nor was he very practical in handling tools; he always got things "fussed up" even in handling nursery toys. He was rather plucky in carrying out things when they were once fully inaugurated, although he was much hampered at any new adaptation not initially planned and provided for. His nervousness, the feelings of inadequacy and doubt once overcome, he got on fairly well in routine duties. He was always very lively and nervously energetic and overactive in play. He was always more or less aware of his peculiarities and has always been rather depressed that he could not do the things he planned as other boys of his age did. He has never been self-reliant and has always leaned on someone for direction, first his father, then his half brothers and sisters. Notwithstanding this fact, he has his own opinions and doesn't depend upon the approbation of others for making or retaining them. Below the surface his egotism is rather strong and dominant, especially when he is greatly provoked or out of temper with anyone who opposes him. He has always been indifferent to dress. (At the early consultations he wore an ill fitting soiled collar and a tie much worn, spotted with stains and carelessly tied; his clothes were unkempt and much disarrayed; his hair was tousled, and he sat in a negligent attitude, although apparently with no disrespectful intent.) He has always been very sincere in his studies, work at home, and in boyish sports. He is always honest and strictly truthful. While he makes much of his nervousness he is never inclined to pity himself nor does he court sympathy. He was always afraid and shy of meeting or talking with strangers as a child, and used to hide himself behind his father when on the street, or ask to be taken up; this continued until he was eight or ten years of age.

He has always been very affectionate toward his father, and seems never to have considered his mother in any way at all; he never voluntarily mentions her, and when she is mentioned he speaks scantily of her. He often said he wished he had the half brothers and sisters' mother for his own, and reproaches his own mother for practically abandoning him to his fate. He has always liked to be with older people, although he seems aware, on the whole, that he may be in their presence only on sufferance and not as an equal; his nervousness is less marked at such times, and their influence is a quieting and soothing one rather than stimulating. He never voluntarily engages his elders in conversation, nor does he elaborate his replies to their questions. When alone, which he is not averse to being, he reads, draws, or day-dreams, as the fancy strikes him. He is fondest of walking by himself, when he builds castles in the air and romances in a peculiarly childish manner. He thus builds or recreates the world and does all sorts of autistic thinking, and at such times he possesses a mythical power of an all-powerful and benevolent God. Of late he has shown more ability to mix with other people, is submissive, and rather constrained in manner, proffering little in the way of ideas or confidences. He prefers younger boys as associates, as he feels more at ease with them, or he selects boys much older than himself for the same reason. He never played freely and naturally with other children, as he was afraid he would not play the game correctly and the boys would make fun of him, which they not infrequently did. He felt a lack of friendly and sympathetic contact with the boy group and was particularly ill at ease with rough boys. Although he makes friends slowly he has a few with whom he feels he is on a footing of equality. This latter feeling tone has, however, been slow in developing, and has taken place within the last year for the most part. He has always been generous and rather overtrustful in friendly confidences. On the whole he is keen in seeing slights where plainly none are intended. He has always been stubborn and inclined to want his own way, although he can be guided a little through his affections. While he is hypersensitive and lacking in tact, he is not offensive or quarrelsome. He has a good deal of common sense in the little affairs of life, but is only superficially satisfied with his surroundings. Of late the patient has grown to keeping to his own council as regards his nervousness, but is very anxious to be relieved of his disorders. Sometimes he is frank about his worries, but is steadily becoming more reticent. He has always been over-conscientious and very religious, usually adhering in a childish literal way to the text of biblical teaching and the dicta of the Catholic Church, to which religion he is much devoted. He has always been rather tender-minded and all his teachers were much amused at his naivete of manner in school work. He is often blocked in activities by various scruples, religious and social customs, which are often raised to an obsessive level of prohibition of whole series of everyday activities. He is very free in his criticism of the behavior of society whenever he thinks it does not square its acts with literal religious standards of conduct and morality. He doesn't, of course, square *himself* to such definite exactions. He has always been slow in mental as well as physical action; it has seemed as though he were checked or blocked by not knowing just how to study or apply himself to any task slightly different from those he has known how to do well. He has never subordinated or automatically adjusted himself to many of the everyday activities, and takes an unusually long time to dress and undress, to eat, and to make decisions which are perfectly simple to most boys of eight or ten years of age.

He is unusually submissive in his friendships, and is very imitative and suggestible to any friendly individual. He is readily taken in by any designing person and has devoted much of his spare time of late in corresponding with catch-penny "ads" in papers and magazines. The last one to engross his attention was a lengthy correspondence with a distant school which promised to teach newspaper and magazine illustrating to anyone in a few weeks. He is not able to keep his spending money long on account of the tempting appeal of the display "ad" promises. In this connection it must be said that personal adornment "ads" concern him little. On the whole, the general mood is one of well being and contentment, with an optimistic outlook in spite of momentary depressions concerning his nervous disorder. The latter make him miserable chiefly at night when he must shift for himself until the next morning and its bringing of companionship with his sister and near friends. He is habitually sober in appearance and facial expression, but can take a joke, although never known to tell one of his own accord. He likes to sing and has a very good voice, but the songs he likes are largely of a somber religious character, often out of keeping with the company he affects. To him the world seems rather serious and tragic, beset with uncertainties for one of his limitations. A certain amount of tedium vitæ has been

present for several years; a *grubelsucht* dates from earliest life (8 or 10 years). His reactions to good and bad news are not especially marked, and sad news never destroys his appetite, cause loss of sleep or emotional outbursts. He is rarely elated, and at such times he may talk rather freely without much show of enthusiasm; it is all over in a few minutes and he quickly resumes his usual quiet, rather perplexed and mildly apprehensive attitude toward friends and strangers alike (seen in the intelligence and look of dumb animals). As he has become older and is forced to rely more on himself he worries more in a fussy way. For instance, when he was to go to a sanatorium in the country last summer for a few weeks' stay during the hot weather, he was opposed to the idea, and worried continually about it, and dreamed about the parting from friends and the unpleasant prospect; but when he actually got there he quickly grew to like it, and this autumn was greatly worried and "fussed up" when he was taken away from it. Real troubles, such as the greatest one, his father's death, did profoundly depress him; he wanted to die and didn't eat or sleep well for several days. He was very emotional at the time. Even ordinary worries seem to strike rather deeply at times, such as meeting his sister or brother at a certain time and place, and on these occasions he gets much upset and all his habits, tics and phobias become marked and extreme. None of these worries last long, however, when once the situation is met or past.

There is no daily or seasoned periodicity in his state of nervousness; it is quite constant except when exaggerated by new adaptations to rather simple situations of living. Although he is not easily frightened, sudden noises affect him profoundly, especially thunder showers and rock blasting in his neighborhood. He used to dwell much on disasters, and believed the San Francisco earthquake and fire happened because the people were so bad; said God had sent a judgment upon them, etc. While he is usually of an even disposition, he is quick tempered at personal slights or fancied ones. If he thinks his company is not wanted he gets very angry, but soon gets over it. He holds grudges for a long time and never makes any amends for mistakes. If handled carefully and talked to in a simple, childish manner he may overlook the fancied slights, but it seems doubtful whether he ever really forgives injuries. For instance, his brother's wife once offended him in making a tactless, though playful remark about his dress. He became enraged, and though he quieted down in a few moments he has never treated her with friendliness since. He said: "Although she has been very nice to me on many occasions and we usually hit it off well, I think of the old remark and hate her more than ever." He has never had any love affairs or fancies, which will seem the less strange when we learn the inner history for this. The patient resembles his mother's people closely in physical and mental make-up. He is much like her, in temperament especially. He was practically brought up by his father. He was always with him when practicable. He is little interested in girls and has never willingly sought their company. In his words: "I can stand them in a mixed company."

Aside from the close attachment to the father, the patient had no strong feelings of friendship or affections for any other person in or outside the family. At fourteen he was led into the habit of masturbation by an elder boy associate; at sixteen he learned the harm of the practice and sought ineffectually to stop it by prayer, cold baths, etc. He never had much sexual curiosity, but gave the whole matter much concern two years ago. It really dates from the latter part of the sixteenth year when he strove to break off the masturbation. The seminal emissions at night are never attended by dream fancies of women. His questions and answers on sexual matters are about those found in the average boy of twelve or fourteen years of age.

To summarize the character-study given, we have here a young man of 19, who was a shy and diffident child, not able to make a broad friendly contact with reality and the social world about him. In the absence of this normal condition he became more constrained and illy adapted throughout early adolescence. As a compensation he grew more shut in, constrained in conduct, and developed a lopsided character. All these characteristics intensified his feelings of inadequacy being blocked by doubts and religious scruples. The sublimation of the dislike and indifference instinct (hate complex) was not overcome by any real push of friendliness and sympathy largely because of the sole and intensive affection for the father. In all, we have a somewhat prolonged detailed description of mental infantilism, whose lack of emotional frankness and development has retarded intellectual advancement and altogether illy adapted the young man for proper everyday life.

Having thus outlined the peculiar but none the less characteristic type of personality-subsoil, we may now build in the details of the tics and obsessions which constitute the so-called disease, but which will be shown really as types of movements and ideas that serve as deeper wishes and longings of the inner life of our patient. In the order of their occurrence the habit movements, tics, and obsessions are as follows:

1. Biting of finger nails following finger sucking.
2. Grimacing tic, involving the whole face.
3. A genuflexion tic.
4. Sighing tic.
5. Laryngeal, clicking tic.
6. Autoecholalia,* which finally ended in (7) an exclamatory tic, "Huh! huh!" a so-called assenting tic.
8. Tousling the forelock of hair, which ended in (9) the finger tic of tousling imaginary hair.
10. Picking the finger nails, which succeeded the cessation of biting the nails.
11. Picking the face, which resulted in a profuse and suppurative acne over the entire face.
12. The ablution tic, wringing the hands and washing the face.
13. Panics and fears that he was to faint, lose his mind, meet with an accident or be killed, or that he is to die.

To some extent one habit movement or tic overlaps the others. At the present time he has eight of these habits and tics. On some days three or four are present only, but on others, when to him great adaptations are called for, they all appear and make the patient's life truly miserable. By glancing at the list it will be seen that the symptoms group themselves largely into those of the face and hands. Without entering into any elaborate argument or explanation, it can be readily seen by anyone who has followed the text of the previous papers that the tics of twiddling the fingers readily goes back to the habit of tousling the hair. The school teacher broke this hair habit, and the finger twiddling tic immediately succeeded. The finger-picking is the result of a failure to bite the nails, which latter habit one of his half-sisters stopped. Before he entirely ceased biting the nails his fingers, in seeking to get to the forbidden goal of the mouth, wandered over the face and reversed the object from nails being bitten to the fingers picking (biting) the face. The laryngeal and grunting tic are the results of trying to inhibit the autoecholalia.

The genuflexion was traced by analysis as a propitiatory act of obeisance as a defense against masturbation as the patient tried to break himself of the habit at sixteen years of age. The ablution tic or habit was traced to the same source. Thus we have the grimacing habit, the echolalia, and the panics and fears of later life to account for. The grimacing tic is the very earliest one and we shall now take up something of the patient's infantile life to note what significance this really had.

The patient's first recollections are of his father's good nature and cheery manner; the father rocked and sang him to sleep, and when the boy was nearly asleep the father carried him to the boy's own room and put him to bed in the dark. He remembers "shutting out the dark by closing the eyes very tight and grimacing at the same time; he made a wry face at the dark"; in this manner he was in part able to soothe his fears of being left alone or parted from the father. He often cried until the father came back with a lamp and sat with him until he fell asleep again. Often the father stole quietly from the room, but the lamp (as a sort of symbol of the father) was permitted to remain in his sleeping room until he was a boy of eight or ten years of age.

For many years all dark rooms made him think of death and separation from the father. At such times he grimaced and shut his eyes tight, and then he seemed near his father. Even when no longer afraid of being alone in his bedroom, forcible closure of the eyes enabled him to shut out reality and make fanciful dreams of being out on larks with the father. The dark meant

*This term is employed to indicate the patient's repetition of some or all of the words in a declamatory statement. An illustration of this peculiar obsessive habit of speech is detailed later in the text.

burglars, violence, his death, and separation from the father. The father also tousled his hair on coming in from the mills and even playfully pulled his forelock until the boy's howls were silenced by renewed caresses.

The young man never had the panics and fears until the father's death. They began soon after. First they came on in the dream; in such the father came back and it seemed as though he had never been ill; then he came in dreams as though he were ill, but recovering; then he returned, was ill, and died; then he returned, was ill, died, and the patient strove to follow him, with all the feelings of the panics and fears. All the dreams ended in a nightmare illy understood until the full drama of the final act in the dream was enacted and brought into the conscious life. Then the father dreams ceased.

He now dreams rarely of the father, but has panics and fears which are, in conscious symptoms, what the pursuits of the father image in death-dreams were. A free association of death brought out an exact description of his panics and fears. All difficult or new adaptations bring on the panics, such as going away from home, meeting strangers or going to little social gatherings. He always had panics when coming to the physician for treatment until the transference took place; now they never appear, and in point of fact the physician image made by closing the eyes and grimacing (voluntary) exorcises the panics. We now can understand that the grimacing and eye tic were expressions of closing out unpleasant everyday reality, and served as a means for getting into closer relation with the father in spirit and probably have even more autepleasurable satisfactions with much deeper meaning which are still to be laid bare. We find the panics and fears are really wish death-symptoms and are used by the unconscious mind to gain the wish of death (often wished and prayed for by the patient) and a reunion with the father—not unlike the apoplexy phantasie of Miss C., detailed in my second paper.

The autoecholalia is still easier to interpret. Inasmuch as the patient has always had doubt and uncertainty of doing and saying the proper thing, he contracted the habit of repeating aloud the essentials of the sentence, the headlines of the idea, as it were, and in this manner he relieved and quieted the doubt and feelings of inadequacy. Much the same was shown later in his underscoring and repeating certain phrases and even ideas in his writing. In the process of inhibiting this disagreeable repeating of words, he first stopped repeating whole sentences, then single words, and now the phenomenon amounts to but a beginning of speech, a sort of exclamatory speech, the former intellectual act has been almost inhibited, but there still remains the semivoluntary muscular larynx and diaphragm contractions. Here we have the complete conversion of a psychic process into a physical act or tic. It has completely lost its former mental meaning.

One sees here in this young ticeur how the doubt mania has widely overflowed its original channel of love for people and gradually extended itself to inanimate things and even abstract virtues of religious tenets. In point of fact, the doubt has become all-pervasive in the whole mental field although as yet it is not very fixed or deep. While one may rightly surmise that there are many surface indications to show the possibility that the ticeur is either physically or mentally homosexual, or both, my cases are not yet sufficiently clear for me to bring forward facts to substantiate this trend. While I have hastily sketched the tic symptoms of this third case study, laying greatest stress upon the defective personality subsoil, the mental infantilism, I trust the genesis of the tic mechanism is sufficiently outlined for one to follow the general theory of development of spasm as we have endeavored to lay down, and that the whole thesis shows the enormous importance of treating all nonorganic tics as forms of the obsessive neurosis. In spite of the tedious length of the three papers, I trust I have made it plain that we must look upon the tic disorder in no other light than a psychoneurosis.

A final word as to the effects of treatment: The young man has, in the opinion of strangers, doubly widened his contact with real life of physical work, play, and study. He has taken up carpentry at an apprentice school; he is punctual, neat, and orderly in routine life. He has ceased being engrossed in the futile efforts to become rich or great quickly by answering ads. He has gained in weight; his face is nearly healed from the disfiguring acne. In short, his physical and mental restlessness, habit movements, tics and obsessions are about half as frequent as at the beginning of treatment four months ago. A few years ago the same degree of progress would have taken two or three times as long by medicopedagogic or inhibition gymnastic training. I shall take occasion to make report on all these cases at the end of a year's treatment.

At the termination of this third paper on tics, the author desires to acknowledge freely his indebtedness to Prof. Freud for his clear and precise analyses of the obsessive neuroses, and the author hopes he has proven that the tic disorders are a part of the general obsessive neurosis as laid down by Freud.

---

The following abstracts, which form the more important part of the discussion of the three papers upon tic disorders, are appended herewith as supplemental criticisms of the theory and its exposition as brought forward in the general text.

Dr. FOSTER KENNEDY said the attitude of neurologists toward many forms of abnormal movement has marvelously altered inside a very short period. The generation which laid the foundations of neurology was concerned chiefly with organic problems, and many of the phenomena investigated were proven to be dependent on gross structural change. This success resulted in the formation of purely organic hypotheses being constructed to explain many facts superficially similar, but in truth intrinsically different. This applied notably to the great group of the tics, which from the time of their first recognition to the present were explained by a score of theories, the basis of most being—nebulously—cortical irritation. Such conceptions naturally led to the application of organic therapeutics, and all of us have seen operations carried out on cases of torticollis and manual tics, with a success often inversely proportional to the severity of the surgical procedures. A complete swing of the pendulum then resulted in the production of a school of medical thought which regarded the psyche entirely apart from the soma, and while the speaker believed that facts would not justify the adoption of such a sweeping attitude, the Viennese School had succeeded in showing the value to diagnosis and treatment of personality studies when added to physical investigation. The personality study by itself was of the utmost importance in unraveling the mechanism of production of many of the neuroses and notably many of the tics, but it did not altogether answer the question: why a particular neurosis should occur in a given individual and not in another individual who has suffered perhaps precisely simiar psychic traumata. For example, Dr. Clark in his account of his last case had most exquisitely shown the various emotional trends which had had their outlet and satisfaction in various abnormal movements, but the speaker would like to ask Dr. Clark if the mother's dipsomania might not have produced in the embryo such changes as would result in an unstable and inferior nervous system in the patient. An innately suitable soil for the production and especially for the growth of a neurosis must be invariably required. There must be an inferior something behind the mere

superficial psychological mechanisms of a neurosis—possibly chemical, secretional, or germ-plasmic in character. However, until in good time we learned to recognize the ultimate factors which went to *differentiate* personalities, we must busy ourselves with trying to *understand* personalities, the deeper springs of which are, as we have seen to-night, often marvelously hidden; as one of the first fruits of such studies we have emerged from darkness to at least an early dawn in our attitude toward torticollis and allied states, and we have to thank Dr. Clark for his large share in leadership in this exodus. Apropos of the modern conception of the immediate etiological factors of torticollis, Dr. Kennedy mentioned the case of a man aged 58, a ship's carpenter in the English Navy, the greater part of whose working life had been spent in cramped quarters watching the movements of a lathe which necessitated a side-to-side movement of his head chiefly to the right. He left the service at the age of 50 and beyond the fact that he was a somewhat nervous, easily excitable individual, he looked on himself as being quite healthy. He settled with his family on a small farm in England. A few years later he saw his son drowned in the river flowing past his land. That night he began to have rhythmical movements of the head so that he was compelled to look toward the right shoulder. These increased in severity and constancy and no ultimate improvement ensued from extensive nerve and muscle resections. This case was seen before the speaker was at all familiar with the newer methods of investigating or explaining such cases, but it has since come to his mind that the movement subconsciously maintained might have been a symbol of the man's desire that he had never left his previous occupation and so had never rented his little farm, all of which events had led up to the death of his son. The resuscitation of the head movements necessary for his old trade acted as a partial fulfilment of his wish that time and circumstance for him had stopped.

Another case was that of a woman aged 42 who since the age of 17 years had had a severe and constant dragging movement of the head to the left, the chin being markedly lowered to the left clavicle. During five years she had received at the hands of innumerable physicians and surgeons every known treatment without any good results having been obtained. She was the only daughter of strait-laced New England parents, with both of whom she is still compelled to live. She had been passionately devoted to her violin and at the age of 16 years created consternation in the minds of her family by announcing her desire to adopt music as a professional career. The result of her attitude was that not only were hopes of the concert platform denied to her, but she was compelled by family fiat to abandon musical study. She became depressed, secluded, brooding, and moody, and within six months from the date of the pronunciamento began to develop the tic described above. It was precisely the head movement necessary for the holding of the instrument now denied to her; we learn that during her depression her real existence was a dream fantasy of musical triumphs, and there can be no doubt of the importance of the part played by her tic in the symbolical realization of her wishes. Undoubtedly both these cases were inherently unstable nervously in many ways not connected with their torticollic states, but a timely appreciation of the mental mechanisms underlying their movements would certainly have prevented much injudicious treatment and might with fair probability have aborted entirely the disease.

Dr. James J. Putnam of Boston said: Every neurologist must have been long aware that, although the so-called tics, even those of the type of torticollis, have sometimes a physical basis, at least to the extent that they can occasionally be helped by treatment directed to the nerves and muscles, and by persistent training, yet this statement of the etiology by no means covers the entire ground. The subject of the mental etiology may, it seems to me, be approached from at least three sides.

1. In the first place we have the important evidence for this view brought forward by such men as Brissaud, Charcot, and Meige, to which attention has abundantly been called.

2. In the next place, each of us has probably had a certain amount of experience bearing out this view. Cases of Huntington's chorea are here in point, and so, also, even if we confine ourselves to torticollis, are cases like the following. I have in mind a lady of about thirty-five, previously of splendid health, and of fine character and courage, who, after the illness and death of her husband (which had brought with them severe trials and the necessity for great self-control) found herself obliged to fit herself for business responsibilities so large that the thought of them might have made many a strong man hesitate. After a year of training, in which she was obliged to keep silent as to her plans, she succeeded in getting on her feet, and then began to be attacked by the series of tics that have pursued her ever since. These began with closure of the eyes, attended by rapid movements of the lids, such as one might see in cases of hysteria of the conversion type. After a considerable time this condition wholly passed away, the recovery being as much without obvious cause as the onset had been. Then she began to suffer from a sort of tic of the lower facial muscles and tongue, and at about the same time, or a little earlier, with a torticollis which corresponded quite closely in its behavior to the mental "type" of the French writers. I did not see her until the disorder had become chronic, and she declined the psychoanalytic treatment which I offered, but accepted other measures that were suggested, and followed them up with great fidelity. It was quite interesting to note, as illustrative of the principle of "transference" (that is, of personal influence) that with each new person and each new treatment there would be an improvement for a time, followed, however, by relapse.

3. Much information can be gained, I think, by enlarging the basis of these disorders through recognizing the similarity and analogy between them and a variety of others. Dr. Clark has, of course, insisted on this point. The nervous habits of the limbs and stammering are instances in point, and so, I think, are many conditions which ordinarily pass for normal. No one has yet tried, so far as I am aware, to go deeply into the psychonalaysis of expression, for the sake of inquiring, for example, why it is that we laugh and cry, etc. The explanations offered by Darwin and the "physiological overflow" explanations are, of course, of great value, but besides this there are obviously emotional causes which are in need of further study. These are circumstances under which even morbid silence and rigidity of expression may be as significant in this respect as are the bent-over attitudes or the open-arm attitudes expressive of well-known emotional states.

Another group of cases which has interested me very much is that very large one where patients and even so-called normal persons, instead of expressing emotional states by movements and in that way finding, as Dr. Clark has pointed out, a sort of outlet for thoughts too deep for words, seek a similar relief through the encouragement of visual phenomena. Thus, many, perhaps most persons, but especially neurotic patients, instinctively seek a relief from nervous tension by combining objects which they see, such as figures on the carpet, on window shades, or wallpapers, or larger objects in the street, or in the room, in geometric patterns, triangles, squares, etc., as if longing to find something fixed and stable for which to exchange their sentiments of instability and doubt. The subject could be almost indefinitely extended, and should then include, among other phenomena, the compulsion to seek relief from nervous tension by constant eating, so well described a few years since by Janet.

Dr. Clark, in closing the discussion, said he believed that there were types of temperament back of the precocious emotions in the infantile life of ticeurs and the other obsessive neuroses and that the disturbance of the ambivaliancy of equality of emotional attachment to each parent was due in greater part to the inheritance of a certain type of temperament which because of its strong determination to the hate polarity made one think that it was really atavistic in component. It would seem to be a predominant trait that many such individuals inherited which was fortunately eliminated in most individuals. While the whole conception of the tics as laid down by him might be somewhat differently formulated in the future, he was confident the essential foundation of the concept would remain.

---

Case of Cerebellar Ataxia.—F. E. Batten reports the case of a girl, aged 5 years, who was quite well till the age of 2½, when she had an acute illness; since that time she has been unable to walk steadily. She now presents the typical picture of a cerebellar ataxia—slow articulation, hypotonia of limbs, no nystagmus, etc. Normal reflexes. When walking she has a tendency to go to the left. She is quite intelligent.—*Proceedings of the Royal Society of Medicine.*

# DETERMINATION OF THE BLOOD PRESSURE AS AN AID TO DIAGNOSIS AND PROGNOSIS IN CERTAIN DISEASES.*

BY ALBERT WOLDERT, M.D.,

TYLER, TEXAS.

It will be recalled that the blood in the human body travels in a circle, and that the time for the complete circuit of the blood to be made in man is about 23 seconds. Approximately speaking, the heart works one-half of the time, and rests the other half. The blood is driven out of the heart into the arteries in distinct pulsations, the arterial walls being stretched at every systole of the heart. During diastole or resting stage of the heart, the elastic recoil of the arterial walls drives the blood forward into the arteries, giving rise to the "pulse," and onward into the capillaries, and this elasticity of the arterial walls spares the heart a great deal of work.[1] The heart of an ordinary sized man does as much work in 24 hours as would be required to lift his body 1,248 yards into the air. The "strenuous life," excessive use of alcohol, and overeating are three of the principal causes of arteriosclerosis met with so frequently at the present day.

The Sphygmomanometer: To determine the blood pressure in man, the sphygmomanometer is now employed. All of the readings (systolic, diastolic, and pulse pressure) of this instrument are determined in terms of millimeters of mercury, or its equivalent when mercury is not employed. The fluctuations of the needle on the dial of a metal sphygmomanometer, are based upon the fluctuations of a column of mercury, placed in a glass tube, or scale. The purpose of the sphygmomanometer is to determine the actual work or force, or propelling power of the heart itself as well as to determine the actual amount or degree of pressure exerted by the blood upon the arterial walls as the blood flows along within the arteries.

Warfield[2] defines blood pressure as being "that force which the contraction of the left ventricle of the heart exerts in propelling onward the column of blood." Faught defines blood pressure "as the term employed to indicate the degree of pressure under which the blood exists while traversing the arteries." High blood pressure does not depend alone upon the work of the heart, since in myocardial degeneration or heart weakness the blood pressure may be actually raised, in this case the blood vessels themselves being overfilled. An increase in the pulse rate does not necessarily increase blood pressure in any condition. Normally blood pressure depends upon (1) the force of the heart and the amount of blood pumped out into the arteries, (2) the resistance in the arteries, (3) the degree of elasticity of the arteries, (4) the volume of blood, and (5) the viscosity of the blood. (Faught.)

A Complete Test for Blood Pressure.—In studying blood pressure, a complete test consists in determining four things: (1) The maximal or systolic blood pressure; (2) the minimal or diastolic blood pressure; (3) the mean blood pressure, and (4) the pulse pressure (range or amplitude). The "mean blood pressure" represents the sum of the systolic and diastolic pressure divided by two. That is to say, if the systolic pressure is 130 and the diastolic 100 the mean blood pressure would be 115 mm. of mercury. The "pulse pressure" (range or amplitude) is determined by subtracting the diastolic pressure from the systolic pressure. Therefore, if the systolic pressure is 140 and the diastolic pressure is 115, the pulse pressure, range or amplitude will be 25 mm. of mercury. In the healthy man from the age of 25 to 50 years, the normal systolic blood pressure has been placed at 105 to 145 mm. of mercury, and the diastolic blood pressure at 25 to 50 mm. of mercury less than the systolic. In my opinion the minimum systolic pressure should more properly be about 100 mm. instead of 105 mm. for adult men. The pulse pressure, range or amplitude varies from 25 to 50 mm. of mercury. In advanced age, such as above 60 or 70 years, a systolic pressure of 160 mm. might be obtained, but this amount of pressure would be considered pathologic in a much younger person. It has been said that a systolic pressure above 150 mm. or below 100 mm. and a pulse pressure above 50 mm. or below 20 mm. of mercury in the adult might be regarded as being pathological. Whether this maximum and minimum figure will hold true remains to be proven. The blood pressure in women is about 10 mm. of mercury, less than for men. Cowing[3] gives the following table for systolic pressure:

Children from 10 to 17 years, 85 to 110 mm. mercury; 18 to 40 years, 121 to 130 mm.; 40 to 50 years, 130 to 135 mm.; 50 to 60 years, 135 to 145 mm.

To remember what the normal systolic blood pressure should be at any age, Faught has formulated the following rule: "Consider the normal average systolic pressure of a male person at 20 years of age to be 120 mm. mercury, then add 1 mm. to every two years of life. The systolic pressure in a person aged 30 years would be 125 mm. and at 60 years would be 140 mm. For females the pressure would be approximately 10 mm. less than for males." The maximum systolic blood pressure being about 145 mm., the young business man or professional man leading the "strenuous life" and having a blood pressure of 145 mm., or with a pulse pressure of 45 or 50 mm., should receive a word of warning, and in which case the blood pressure should frequently be taken. The pulse pressure (range or amplitude) is of much importance in the study of cardiac muscular inefficiency (myocardial degeneration) and valvular diseases of the heart, and especially regarding the prognosis of such conditions. In these instances an exceedingly high, or an exceedingly low pulse pressure, portends evil.

A temporary or transient rise in the blood pressure—either systolic or diastolic might not necessarily indicate disease, but when the blood pressure is *constantly higher* than normal the condition is regarded as being pathologic.

For this reason to obtain accurate results with the sphygmomanometer the systolic and diastolic blood pressure should be taken more than one time, and on different days, and at the same relative time of day, and under the same conditions. A slight variation occurs from day to day in the blood pressure in any individual case, but this maximum should not, as a rule, be above 10 to 15 mm. of mercury. Hypertension means the alteration in which the blood pressure remains constantly above the normal, and hypotension when the blood pressure remains constantly below the normal.

*Read by invitation before the Dallas County Medical Society, Dallas, Texas, December 15, 1913.

Method of Taking the Blood Pressure.—Blood pressure readings are now obtained from pulsations of the brachial artery just above the bend of the elbow. The arm should be bare and the left arm selected. The standard cuff to encircle the arm should have a compression surface of 4½ to 5 inches (11 to 13 cm.). If the cuff is narrow the readings will be apt to be higher. Before taking the blood pressure the patient should be requested to take a rest of 10 to 15 minutes. After doing so the left arm is bared and the patient allowed to be seated (if not too ill), with arm resting upon a table or desk, and the arm relaxed, being about on the same level with the heart. The cuff is then adjusted smoothly around the arm, and if made of silk the tip end left after rolling should be tucked under the folds. Care should be exercised to see that the rubber bag of the pad fits directly over the brachial artery. The systolic pressure in the standing position is 2 to 6 mm. higher than when sitting down and 6 to 10 mm. higher when standing than when lying down.

The systolic blood pressure should be taken first; then, working very quickly and carefully, the diastolic pressure should be taken. Prolonged pressure of the pad at times seems to change the pitch of tone of the artery and occasionally makes it almost inaudible. To obtain a check on the results obtained at the first reading about 5 or 10 minutes should elapse, and a second reading then made, taking the systolic pressure first. More correct results can be obtained as stated by taking the blood pressure on several successive days. The auscultation method of determining blood pressure is to be preferred to any other method. In listening for the sound of the brachial artery the bowl of the stethoscope should be placed directly in the center of the bend of the left elbow, below the pad, and, while the arm is relaxed and elbow bent at an angle of about 20 to 30 degrees. The arm should not be rigid.

Conditions Which Influence Blood Pressure.—As stated by Faught[4], the blood pressure is influenced normally by (1) age, being higher as old age advances (the saying "A man is as old as his arteries" is almost a truism); (2) sex, being higher in the male than in the female; (3) time of day, the blood pressure being slightly lower in the early morning hours than toward the afternoon or evening; (4) size and temperament, in highly nervous persons the blood pressure being high; (5) digestion, the blood pressure is believed to be slightly higher after meals; (6) muscular development (in the muscular person the blood pressure is believed to be some 5 to 10 mm. higher than in the weak person; (7) muscular exertion or exercise (exercise raises the blood pressure, and this rise might be sudden and sharp, amounting to 5 to 15 mm.); and (8) mental anxiety or fatigue; fatigue after prolonged exercise or exhaustion lowers the blood pressure. To these we may also add (9) position of the body, the blood pressure being lowest while lying down, somewhat higher in the sitting position, and highest of all while standing; (10) altitude, Faught being of the opinion that considerable reduction in the barometric pressure in a high altitude lowers the blood pressure of persons in health, but in the tuberculous the blood pressure is increased. Peters and Bullock in a study of 600 cases state that at an elevation of 6,000 feet the blood pressure is increased, and that in persons in health, and consumptives the blood pressure is higher at 6,000 feet than at the sea level. Prolonged stay in an altitude of 6,000 feet seems to increase the blood pressure up to certain limits; (11) bathing (water, either hot or cold, applied to the surface of the body has been found by most observers to cause at first a transient rise in blood pressure, soon followed by reduction in blood pressure. Hinsdale says: "Baths between 95° F. and 104° F. produce a preliminary rise; a secondary fall below normal, then a rise. Baths above 104° F. increase the blood pressure and slow the pulse rate, the pressure remaining high."

When the blood pressure is already too high (hypertension) the application of a sudden cold bath, such as a plunge into the sea, might become dangerous on account of the tendency to produce a rapid rise of blood pressure resulting in heart failure, or rupture of a blood vessel in the brain, causing apoplexy.

The Different Sounds Noted in the Brachial Pulse in the Change from the Systolic to Diastolic Phase.—Stone[5] describes the different tones or sounds heard over the brachial artery by means of a stethoscope after compression by the cuff as follows: first phase, a phase of clear tones which is soon replaced by the second phase; second phase, a phase of muffled tones with a series of murmurs; third phase, a phase of clear tones (the diastolic phase), which suddenly becomes markedly dull; fourth phase, a phase of dull tones; fifth phase, disappearance of all sounds. It has been shown by Fischer, Lang, and Manswetona (1908) and proven by Warfield (1912) that the diastolic blood pressure coincides with that point at which the *third phase of clear loud tones becomes suddenly and markedly dull.* Miller (1913) agrees with the view of Fischer and the other writers. The diastolic blood pressure, therefore should *not* be taken at the time of disappearance of all sounds of the brachial pulse (fifth phase), but only at the third phase of tones or where the clear loud tones suddenly become markedly dull.

How to Determine the Systolic or Maximal Blood Pressure with the Mercury Sphygmomanometer.—(Riva-Rocci-Cook's modification, Faught, Janeway, etc. The Riva-Rocci instrument must be provided with a rubber cuff covered with silk, see dimensions above).—In order to determine the systolic blood pressure, either one of two methods may be followed—namely: (1) The auscultation method, which is the one to be always preferred, or (2) the palpation method.

The Auscultation Method: The rubber cuff with silk covering is applied smoothly around the arm just above the bend of the elbow, the tip of the cuff being tucked underneath the folds of the silk band, and the rubber cuff is distended with air. As this is done the column of mercury is seen to gradually ascend in the glass tube or scale, due to the pressure of air in the rubber bag or cuff and pressure against the tissues below the cuff. The end of a Bowle's stethoscope is now pressed lightly in the center of the bend of elbow and directly over the brachial artery, or at that point (half inch below bend of elbow) where the brachial artery bifurcates into the radial and ulnar arteries, and the air is forced into the cuff until the pulse ceases to be heard, and so continued until the column of mercury is forced upward some 10 mm. above the point where no sound of the pulsating artery can be heard. The air in the cuff is now very carefully and slowly released (or through yielding of the

rubber tubes if, Riva-Rocci instrument) when the mercury column gradually descends until a loud sharp "thump" of the returning pulse is heard, and the precise mark on the scale where this first loud "thump" is heard marks the point of *systolic blood pressure.* If there is a high bifurcation of the brachial artery the bowl of stethoscope must be placed slightly above bend of elbow. If the sound of the brachial artery cannot be heard at either of these regions, the sound may sometimes be brought out more clearly by removing the cuff and swinging the arms around, as in taking calisthenic exercises. If the sound of artery is not brought out after this mild exercise the palpation method must be employed. In listening for the sound of brachial artery as previously mentioned the arm must be relaxed, and elbow bent at an angle of about 20 or 30 degrees.

The Palpation Method with the Mercury Sphygmomanometer.—After applying the rubber cuff above bend of elbow as described, place two fingers over the radial artery at the wrist. Air is then forced into the rubber cuff until the radial pulse can no longer be felt by the palpating fingers and by forcing more air into the cuff the column of mercury is forced about 10 mm. above the point where the pulse first becomes obliterated. The air in the cuff is now very gradually released (or until yielding of the rubber tubes if Riva-Rocci instrument is used), and the column of mercury is allowed to very slowly descend. At first the radial pulse will return very weak and thready, and that point where the first full and bounding pulse is felt marks the *systolic pressure.*

How to Determine the Diastolic or Minimal Blood Pressure with the Mercury Sphygmomanometer.—(Faught, Riva-Rocci—Cook's modification, Janeway, etc.) To determine the diastolic pressure with the mercury sphygmomanometer there are two methods: (1) The auscultation method, which is the one to be always preferred, and (2) the visible method (Riva-Rocci, with Cook's modfiication).

The Ascultation Method of Taking the Diastolic Blood Pressure.—Apply the cuff above the bend of the elbow as usual and listening at the sound of the brachial artery with stethoscope placed below the cuff take the systolic blood pressure. The air in the tube is now allowed to gradually escape (or through yielding of the rubber tubes if Riva-Rocci sphygmomanometer is used), when the column of mercury slowly descends until the loud, clear sound of the brachial artery *suddenly becomes markedly dull* (third phase of sounds), and the occurrence of this dull sound denotes the *diastolic blood pressure.*

(2) The Visible Method of Taking the Diastolic Blood Pressure with the Mercury Sphygmomanometer (Riva-Rocci—Cook's Modification.)—Take the systolic blood pressure and release the air in the cuff, or through yielding of the rubber tubing the mercury in the glass tube slowly descends, and bounding upward with each pulsation of the artery (the mercury rising and falling), and at that point where the movement up and down of the mercury in the glass scale suddenly becomes less, marks the point of *diastolic pressure,* the lowest point on scale or base of excursion of mercury being selected. This visible method I have confirmed by the auscultation method, and by the oscillation method with sphygmomanometers other than mercury.

The statement has meen made that it is an impossibility to take the diastolic blood pressure with a mercury sphygmomanometer for the reason that mercury requires 1½ seconds to recover itself, while in one second of time there will have been 1¼ heart impulses. But this objection I have found is doubtful.

On November 25, 1913, I made a comparison of the results obtained in two persons in health (and each 27 years of age) with the Tycos and Faught metal sphygmomanometers (oscillation method), and the visible method with the Riva-Rocci instrument with a wide silk cuff, as above described, and my results were as follows:

No. 1 (adult male).—Tycos—Systolic, 105 mm.; diastolic, 85 mm. Riva-Rocci—Systolic, 105 mm.; diastolic, 88 mm.; Faught—Systolic, 100 mm.; diastolic, 80 mm.

No. 2 (adult female).—Tycos—Systolic, 98 mm.; diastolic, 82 mm. Riva-Rocci—Systolic, 92 mm.; diastolic, 74 mm. Faught—Systolic, 88 mm.; diastolic, 68 mm.

A second test made with Riva-Rocci instrument gave in No. 1 systolic 104 and diastolic 80; a third reading with same instrument gave systolic 104 and diastolic 80 mm.

The Methods of Determining the Systolic Blood Pressure by Means of Sphygmomanometers, Other Than Those Using Mercury As An Indicator. (Tycos, Faught).—To determine the systolic pressure with such instruments there are two methods: (1) the auscultation method (which is the one to be preferred); (2) the palpation method.

The Auscultation Method.—The rubber bag or cuff is applied around the arm just above the bend of elbow as usual, and the end of a Bowle's stethoscope is placed below the cuff over brachial artery in median line at bend of elbow, and air is forced into the rubber bag or cuff until the pulsation in brachial artery can no longer be heard. Continue to force air into cuff until the needle on dial runs up about 10 mm. above the point where the sound of pulse becomes obliterated, and then gradually release the air in the cuff, and the needle descends on the scale until a loud "thump" of the returning pulse is heard, and the needle on the dial read at this moment, marks the *systolic pressure.*

Palpation Method.—Is the same, as when mercury sphygmomanometers are employed (see above-palpation method).

The Methods of Determining the Diastolic Blood Pressure by Means of Sphygmomanometers, Other Than Those Using Mercury As An Indicator. (Tycos, Faught).—To determine the diastolic pressure by such instruments there are two methods, namely: (1) auscultation method, and (2) the visible or oscillation method. The auscultation method (the method to be preferred).

After the cuff has been applied in the usual manner, place the end of a stethoscope below the cuff over the brachial artery at bend of elbow and take the systolic pressure, then gradually release the air in the cuff 3 to 5 millimeters at a time until the loud clear tone *suddenly* changes to a markedly *dull tone* (3d phase), and the lowest point of the excursion of the hand on the dial while oscillating marks the *diastolic blood pressure.* This reading must be made the instant the loud clear tone suddenly changes into a markedly dull tone. On November 24, 1913, I made a comparison of the results obtained by the auscultation method with the Tycos, Riva-Rocci (Cook's modification), and the Faught sphygmomanometers, in person No. 1 reported above, and the results were as follows:

Tycos, systolic, 102; Riva-Rocci, systolic, 106; Faught, systolic, 102; Tycos, diastolic, 84; Riva-Rocci, diastolic, 84; Faught, diastolic, 84.

The second reading made with Riva-Rocci was: systolic, 104; diastolic, 84 mm.

The Oscillation or Visible Method of Taking the Diastolic Blood Pressure with Faught or Tycos Sphygmomanometer.—Apply the cuff as usual and take the systolic pressure, in the manner described above, and when this has been determined, slowly release the air in the cuff 3 to 5 millimeters at a time, and at the lowest point of the greatest excursion of the needle on the dial taken when it is swinging at its greatest excursion (maximum oscillation) marks the *diastolic pressure*. (See results obtained by oscillation method with different kinds of sphygmomanometers.

The Importance of Taking the Diastolic Blood Pressure.—In view of recent investigations made it now appears that the determination of the diastolic and pulse pressures are of almost equal importance to the systolic pressure. According to Stone,[5] the systolic and pulse pressures represent myocardial values, while the diastolic pressure signifies arterial resistance. The pulse pressure alone represents the intermittent burden of pressure imposed on the arteries by the heart's energy during systole in order to force the blood onward to the periphery and maintain the circulation. The pulse pressure therefore represents that part of the heart's energy which produces distension in the arteries and recognized as the "pulse." As further stated by Stone, the pulse pressure shows the "load" and "overload" of the heart. If the systolic pressure would be 120 and the diastolic pressure 80, the pulse pressure or load of the heart would be 40 80 or 50 per cent, of the diastolic pressure. In 61 normal people Warfield found the average pulse pressure to be 40 mm. Stone regards the normal load of the heart to be 50 per cent. of the diastolic pressure. If the systolic pressure is found to be 170 mm. and the diastolic 100 this would be 70 minus 50 or an overload of 20 per cent. When the pulse pressure is over 50 per cent. of the diastolic pressure he considers the heart "overloaded" and there may be danger of myocardial exhaustion at any time from slight strain. The greater the overload the greater the danger. In myocardial fatigue if the pulse pressure falls to 15 to 20 mm. of mercury, he believes that actual circulatory embarrassment has already occurred. The danger from surgical operations in such cases is referred to by Stone who reports a case in which the systolic pressure was 145, the diastolic 75 mm., or a pulse pressure of 70 mm., or an overload of 25 per cent. In one instance the heart load was 93 per cent., or an overload of 43 per cent., and in this case an operation was performed, one lobe of the thyroid being removed, and the patient died five hours afterward, gas-oxygen anesthesia being used.

The Blood Pressure in Heart Disease.—It has been stated that the sphygmomanometer may show evidence of cardiac disease before the development of a murmur. In beginning myocardial degeneration (myocarditis) there may be an irregular rhythm of the heart and the blood pressure may be high in some cases, and Faught says this latter sign comes on earlier than any other condition noted. Very late in this affection the blood pressure falls. If the pulse pressure be over 50 per cent. of the diastolic pressure in myocardial degeneration failure of the heart may occur. As a further means of diagnosis of myocardial degeneration the Graupner and the Schapiro tests may be employed and as referred to by Faught. The Graupner test consists in having the patient while standing take mild exercise, such as bending over ten times and touching the floor with finger tips. In normal persons there should be a slight rise of blood pressure, but with a failing heart the blood pressure falls. This test might be dangerous in those patients who are much weakened, or in whom the systolic pressure is over 200 mm. The Schapiro test consists in comparing the number of pulse beats per minute while standing with the number while lying down. Faught says that normally the pulse rate while standing is 7 to 10 beats faster than when lying down. In the case of a failing heart the irregular pulse may be as fast in the recumbent position as the standing. In organic heart trouble when the compensation is good there may be no change in the normal blood pressure for the given individual, but if the pulse pressure should suddenly mount up to 50 or 60 mm. it might indicate an overloaded or failing heart with a warning of loss of compensation and make the prognosis more unfavorable. Faught says that in aortic regurgitation the blood pressure is unusually high and is accompanied by a low diastolic pressure giving rise to a high amplitude (pulse pressure) said to be quite characteristic of this condition. In mitral stenosis the blood pressure is low on account of the small volume of blood passing through the valves from left auricle into left ventricle. Disease of the mitral valves may show no change in the blood pressure. Valvular disease of the heart tends to myocardial degeneration. To determine whether or not a cardiac stimulant such as tincture of digitalis is producing the proper physiologic effect the blood pressure should be often obtained.

The Blood Pressure in Pregnancy.—During pregnancy the blood pressure should be frequently taken. In 100 nonpregnant women Hirst[6] found the normal pressure to be 112 mm. In another series of 100 pregnant women he found the systolic pressure 118 mm. up to the seventh month, when a gradual rise occurred until the last month of pregnancy at which time the systolic pressure averaged 124 mm. He found that one of the earliest and most constant signs of toxemia in the latter half of pregnancy was a constantly increasing high blood pressure, and this symptom preceded the occurrence of albuminuria in those cases in which eclamptic convulsions occurred.

The Blood Pressure in Life Insurance.—At the present time life insurance companies hesitate to accept a risk of the adult when the systolic pressure is over 150 mm., or under 95 to 100 mm. Fisher[7] found that in a series of 2,668 persons insured in which the systolic pressure had been 140 to 149 mm. there had been 31 actual deaths or 37 per cent. of the table. Of 782 persons declined for insurance in whom the systolic pressure was 171.03 mm. there were 32 actual deaths or 155.27 per cent. of the table. In taking the blood pressure for life insurance companies it would be always best to determine the diastolic as well as the systolic pressure. The most favorable time to take the blood pressure would be in the morning several hours after a meal, and after the applicant has taken a rest of 10 to 15 minutes.

The Blood Pressure in Surgery.—In abdominal surgery it has been suggested that if the systolic

pressure falls to a point below 100 mm. that the operation be stopped and salines used to prevent further shock. Shock during operation or hemorrhage after operation is manifested by a sudden fall in the blood pressure and increased pulse rate. During ether anesthesia if the blood pressure should fall suddenly and the pulse rate rise, one should look out for danger from further shock. Nitrous oxide causes a high rise in the blood pressure; ether, a moderate rise from the very beginning and continuing unless the heart begins to fail; chloroform produces a fall in the blood pressure from the very beginning of its administration to the end; nitrous oxide combined with oxygen produces no effect on the blood pressure, unless the operation is prolonged. It has been stated by Cowing[3] that cataract occurring after middle life is always indicative of arteriosclerosis and the blood pressure is high and Peter was of the opinion that intraocular hemorrhage after cataract extraction was due to the hypertension present. In glaucoma Cowing found the blood pressure high and seems to be of the opinion that hypertension might be a factor in the production of glaucoma.

The Blood Pressure in Bright's Disease.—In chronic interstitial nephritis the systolic pressure is persistently high (175 to 250 mm.) together with a low diastolic pressure, and these clinical signs found with the sphygmomanometer are said to be present even before the occurrence of albumin or tube casts in the urine. In parenchymatous nephritis the blood pressure does not seem to be so materially increased.

Janeway[8] says that in a study of 500 persons showing a systolic pressure of over 170 mm. seen by himself and father during eight years, 150 of these patients were known to have died. For 100 of these he obtained the cause of death and of these 100 cases 79 died of nephritis. In 220 cases of diabetes seen by Janeway 50 showed a high blood pressure, doubtless being due to the supervention of nephritis. In diabetes ordinarily the blood pressure is said to be reduced and often below 100 mm. Of 53 cases who died of different diseases and went to autopsy at the Massachusetts General Hospital, in which the systolic pressure was over 160 mm. Lee[9] reports that some kidney lesion was found in 38 cases or 71 per cent. All of the patients with persistent systolic pressure of over 200 mm. showed some kidney lesion. The results obtained by Lee were also confirmed by Miller.[10]

In my experience the sphygmomanometer is of great advantage as an aid to the diagnosis of Bright's disease, especially when there is no microscope at hand, for in this condition the blood pressure will generally be found above the normal. Of several patients who have come to me for treatment and who imagined they might be suffering from kidney trouble, my examinations showed that in nearly every instance, when the systolic pressure was normal I found no albumin or tube casts in the urine, while in other instances when the systolic pressure was over 175 mm., both albumin and tube casts were present. In one adult I found the systolic pressure 100 mm., and both hyalin and granular casts, but this low blood pressure was doubtless due to a late stage of myocardial degeneration death occurring soon afterward.

Until a few years ago the subject of blood pressure received only slight notice, but now since the findings determined by the sphygmomanometer have proved to be of such real merit that the more careful physician in his every day work might hesitate to risk a diagnosis, or prognosis in certain diseases unless his opinion has been first confirmed by the results obtained by this instrument.

## THE TRAIL OF THE SERPENT.*

BY G. K. DICKINSON, M.D.,

JERSEY CITY.

ARISTOTLE said the most difficult thing for man to learn was to be secret and silent. Probably this accounts for the high esteem the serpent held in the minds of early man. No animal more quietly nor more gracefully carries itself over the ground, through the leaves, and away from danger. It is clean, slick, pleasing in curves, never obtrusive. Primitive man, given to deification, seeing in all life a symbol, a sign, or an indication, would naturally attribute to the snake the qualities which befitted the characteristics appreciated. In its gentle, quiet, sinuous movement was discovered subtlety. In its ability to quickly and easily pass from sight without evidence of haste or means of motion was seen wisdom. The casting off of its skin at intervals led to ideas of regeneration, immortality, and eternity. Some of the early sects deified it to such an extent that it was personified with qualities of kindness and virtue.

We find the serpent associated with three professions which held prominence with the people. It twines on the rod of Æsculapius. Whether the rod be a limb of a tree or phallyc expression, the serpent typifies wisdom, healing, and life. With the tripod of Delphus (the shrine of political prophecy), it indicates cunning and cleverness. At the shrine of Cassandra, whose prophecies brought trouble and foretold disaster, the serpent denotes subtlety.

Thus we see the snake associated with learning, wisdom, magic, cunning, religion, and deification. However, the belief in the serpent was not held by priests and soothsayers only, but it was evidently held largely by the people. The earliest treatment for disease discovered in writings in the tombs was an amulet made to represent a serpent.

For many hundreds of years medicine as practised and taught was amalgamated with the religions, philosophies, and magic of the day. This was not only because primitive man had so little else for mental entertainment, nor was it because man of that day was not as bright and intelligent and keen as in later periods, but because mankind himself tends naturally to religion, to the mysterious, and to that which appeals to the senses and is easily appreciated by ordinary mental processes.

*Read before the Medico-Surgical Society, January 17, 1914.

In the beginning of things pains and distresses were instinctively treated by each individual, undoubtedly very much as animals treat themselves to-day, and, with the community spirit, sympathies were aroused and endeavors made to relieve the complaints of others. As minds developed and experience increased, merely passive attention to body ailments was augmented by the use of such herbs as by their appearance appealed to the individual, or through chance usage happened to be associated with relief of symptoms. A large experience in the employment of roots, leaves, etc., must have been obtained, and with crude reasoning a correlation of effect noticed. The principal disorders in the life of primeval man undoubtedly were the result of gluttony or indiscretion of diet, and, as many herbs have an enemetic or cathartic effect, relief would follow.

Minds becoming more developed and reasoning powers enlarged, a natural delving into the cause of distresses ensued. Pains were brought about by the presence of the evil one. To be sick was to be possessed of the devil. This was the logic, therefore the remedy was to dispossess the body or the member of the presence of this unwelcome guest. All early therapy is suggestive of methods of attack and defense—the rubbing of the part was to rub out the devil that was in it, and the relief obtained seemed to prove the reasoning correct.

As time progressed, the treatment of disease fell to those who were the wiser ones of the day, and being largely speculative and associated with religious emotions, we find an amalgamation of religion and philosophy. Being poorly comprehended and leaning to the mystical in treatment, the magical was ascribed. So we see that the foundation of medicine was closely related to philosophy as well as to the magics, and things not understood were deemed supernatural. The knowledge pertaining to the healing art of that day was obtained through chance and empiricism.

The origin of civilization is believed to be in Mesopotamia. Our earliest records date back some four thousand years B. C. The life of the people there, their method of government, their social and political views, their incomplete knowledge, all tended to foster this composite of the several clubs; medicine, speculative philosophy, and the magical. Individualism, new thought, and development were suppressed. There was little tendency toward branching out. Beliefs were entirely connected with the senses. Things seen were connected with conditions felt. The onset of disease was ascribed to the state of the moon, to the position of the stars, or to the passing of birds. Natural occurrences led to fantastical reasoning. A special divinity or demon was ascribed as the cause of individual unexplainable conditions. Sickness was looked upon as a punishment for evil doing. Dreams were remembered and considered as the visitation of spirits portending good or evil. So in the medicine of those days, the visitation of the evil one was met by religious exercises. The mystical was treated with magic. All disease was mystical. All cure was magical. Therapy was to break natural laws rather than to aid Nature.

The cure by magic was the earliest known. Amulets were worn in order to pacify the evil one. Parts of other animals, teeth, claws, and paws were carried in order to turn away the evil one and protect one from illness. Superstitions were so great that a potent influence was supposed to be obtained through them. The same as to-day we see the horseshoe over the door, the scapula, the amber beads around the neck, the rabbit's foot, and the potato kept in the pocket to ward off rheumatism.

In the religious method of treatment we have sacrifices and fumigation to appeal to the ritualistic sense, and through these hundreds of years we find that man's nature is not satisfied except he unbend to this great tendency to ritualism, fumigating, burning, and destroying. Fasting and persecuting the body cleared the alimentary tract and satisfied religious thought, hence the present-day Lent. Blood-letting to allow the demon to come out; cupping to draw it from some particular region; massaging to drive it away—these are all religious ceremonies and were conventional in the early days and explained by the theologian.

Certain men were more clever than others. They believed in themselves. They believed in their treatment, and the more others believed in them the more satisfied they were in their conceit. These men withdrew from the society of others. Their minds became narrowed. They speculated in philosophy. They experimented in medicine. They held the populace by their mystical methods.

In course of time civilization and knowledge passed over into Greece. Here we find a different people and a different government. Instead of a monarchy we have an approach to a democracy. Instead of suppression of thought we find thought individualized. Instead of mystery we have broad culture. And here for the first time we find marked individual prominence, associated with gradual separation of the three fundamentals of medicine, philosophy, and practice.

Plato was the exponent of speculative philosophy; Socrates the exponent of applied philosophy. In Hippocrates we see that wonderful development of mind which occurs but rarely in the history of civilized man. Considering the knowledge of the day, his surroundings, the tremendous and overwhelming influence of existing conditions and the knowledge of medicine evinced by him, he seems the greatest man of all time. The big men of medicine through all history have been hippocratic. They were known as healers, but they were really students of symptoms. The work of Hippocrates is one grand illumination of the symptoms and signs of disease states. His philosophy is aphoristic and not speculative.

The impetus given to medical thought and medical growth dates back to ancient Greece. From this land of freedom and potent mentality medicine passed over to Egypt, where under conditions existing there another aspect of medicine developed—preventive medicine. The wonderful chapters on sanitation in the Bible undoubtedly had their origin in the laws of Egypt.

It is not to be believed, however, that medicine had entirely separated itself from its incubus of primitive times. The history of medicine is largely made up of the lives and doings of its prominent men. True medicine should be considered properly from the evolutionary standpoint and should be developed from the common beliefs and customs. It should be viewed from the outside, not from the professional side. It is not as we see ourselves or like to see ourselves, but as the public sees us that we should be judged. Medicine had not even then thrown off the shackles and become independent of magic or theosophy.

After the birth of Christ Rome enlarged. Communication with distant countries was opened up

and the philosophies carried abroad. Then came cross-fertilization of minds of different types, tendencies of various kinds, an dthe stimulation of several climates, but theology did not let go its hold. All the other philosophies were suppressed and medicine with them, and for a long period there was no great growth in medical thought or therapeutic action.

The Christian religion appealed to the senses as did no other. As in political life the rulers and those in power were desperate autocrats, selfishly excluding those of other opinions, so all previous religions had been those of fear and awe rather than of love and simple faith. The sage and the peasant were carried away with it, and for many centuries it occupied the minds at the expense of all other lines of learning. Theology grew wildly, as had medicine in the past. The controversies were fierce and concerned not only the mind but the body. Time was given up to the discussion of religious matters and beliefs and medicine and all the sciences were relegated to the background.

Growth of mental activities can be compared with the growth of the body. It must pass from infancy to adult productive life, and only at the end do we find the fruit, the result of vitality of roots and leaves. So, Christianity delivered the soul to a faith; the French Revolution delivered the body politic in hope; while the Renaissance made for intellectual charity for all. And in the Renaissance we come to the time when the tree of knowledge began to bear fruit—the period of criticism.

Versalius, in his pointed, accurate, and destructive attack on Galen, was the first physician to open up paths illuminating the science of medicine. From his time the history of medicine shows an increasing number of those who ceased to look upon disease condition as a morbid entity, chemical, physical, or supernatural, for even then there were prominent men who felt that after the fashion of Galen they could explain bodily discomforts and defects as simple obsessions, but their theories were quickly controverted, short-lived, and but steppingstones back to the truth. They were mainly relics of the old tendency—philosophical discussion rampant with wild logic or tinctured strongly with religious thought or attempt to explain everything by literal interpretations of the Bible.

In Sydenham we have another Hippocrates; a man of large mind, clear logic, keen observation, and an innate ability to dislodge the fetters of the past and appreciate the idleness of theory and the value of individual observation. Like all great men, he was ahead of his time. His contemporary, Boerhaave, with equal acumen, appreciated the position of Sydenham but saw the necessity of studying the ancients to comprehend their minds (placed as they were in semi-darkness) in order that a comparative study might give additional impetus to medical knowledge.

These three men were the saviours of medicine. Their great work, their prominence in the profession, the great change coming over all Europe, and the timeliness of their expositions placed medicine on the crest of a wave that carried it way beyond the dangers of speculation, religious autocracy, and the deductive meddlesomeness of magical superstition.

But how about the medicine of to-day? What are *our* faults? What will be said of us a hundred years hence? How will our history be written? Are we as placid in conceit and self-satisfaction as were the men of olden times? Are we swayed by the prominent thoughts of the day? Perhaps we are on the pendulum. Perhaps science in time may be considered as deleterious and perverting to true medicine as even the several frames of mind enunciated. Are we taking proper advantage of all that pertains to relief of body ills? Are we not still in the thrall of Galen?

A hundred years or more ago Hahnemann noted that certain drugs given in small doses produced an effect quite similar to the disease which it might cure, and instituted the doctrine of similars. Had he been satisfied with this truthful and simple observation homeopathy would have held its own, but, like most parents of single children, his mind wandered, he overestimated its importance, and his theorizing passed beyond the ground of fact and reason. He ascribed to medication dynamic spirits possessing power over disease states and by attenuation, rubbing, and shaking of solutions he claimed to be able to liberate the spirits so they might have a more positive effect.

This was in Germany, where the people were tired of blood-letting, purging, nauseous medicines, and coming to their own in other ways through the Reformation, and the homeopathic doctor soon became popular because he gave the same promise and his medicines were more pleasant. From then on this deistic medicine held sway not because of its theory, but because true medicine was altogether disagreeable. This is the beginning of the supremacy of the patient over the physician.

Schlatter, in this country, noting that the medical profession had carelessly allowed massage to decline and had turned it over in large part like obstetrics of old to women, and seeing his opportunity to attain fame and livelihood, developed another bogus theory of disease in order that active dynamic massage might be exploited for the benefit of its cult and the patient. His theory was irrational, but in a sense clever, because here again the medical profession had been thinking of themselves and their own knowledge and forgetting the patient. Like all quackery it will soon die out and medicine in its slow amebic way will have given to it another process of treatment which it had neglected.

What we have learned from the irregular in these two instances we have been compelled to learn from others at various times. As Galen worried because there were half a dozen dogmatists in his day, so now we have forced down our throat truths from the Christian Scientists and members of the Emmanuel Movement.

One schism has arisen of late years which appeals to the senses as magical and being weird is much in vogue with surgeons and physicians as objective therapy, and that is, spectacular electricity, great promise being given of cures.

Therapeutics as taught in the schools is very largely the therapy of drugs, and the young man leaving college sees in each medicament a specific action. Philosophically to each drug is ascribed a supernatural action. It is entertaining to watch the therapy of the average practitioner of to-day, young or old, and to note the deification, as it were, of the medicines he is using. He stimulates his patient with a cocktail of therapy and an abundance of faith that makes one wonder at the credulity of the public and the calm tolerance of the medical profession. One man is having a lower death rate than all his friends because he is giving aconite to every case of pneumonia; another man with equally lax

philosophy has a belief in the magical effect of belladonna, and is congratulating himself. Look at the wonderful cure and reliefs obtained through antiphlogistine. How it is controlling appendicitis, pleurisy, and other inflammatory states! Our therapeutics is not made by our brains through careful study but is brought to us by the traveling salesman who tells us what we should do and very often we do it. There never was a clergyman who dropped theology and became a competent physician, neither can we with incomplete knowledge of drug action, through supernatural agencies, force medicines to cure disease states. Nature must be aided and such therapy disturbs her in her processes.

What greater reproach could there be to the healing art than the tremendous size of our National Standard Dispensatory? How well we know that there are a very few medicaments that can heal and cure. How resigned we must be in many a case as we stand by and feel ourselves powerless as lesions advance! We are judged by our promises and is not our massive pharmacopœia a sort of guarantee to the people of a vast importance we cannot stand for?

Surgery even demonstrates abhorrent philosophy and a sanctified scalpel, evidenced by the frequency with which ovaries and appendices are removed for right-sided pain, the pain not being removed, and the readiness to use the knife on meager symptomatological study. We have seen normal colons removed without any satisfactory demonstration that efforts had been made on logical lines to control intestinal stasis. The work of the scalpel has been carried too far in our nomad societies. One of our leading societies until recently held exhibitions of skill in special work in the town of reception. Almost without exception the operator was nervous and disturbed by an unusual audience. Mistakes were made and unnecessary deaths resulted. If we are credibly informed, the Surgical Congress is soon to be discontinued and one of the reasons whispered is that the death rate is saddening.

Perhaps when our history is made up in true perspective some generations hence we may be accused of being too pathological and too scientific in a terminal sense. What the eye sees makes the strongest impression. The lesion of the autopsy room has been overworshipped. Terminal pathology has dictated lines of thought and systems of cure. There may be as much insanity in the pathological era as in those of the past. If we read aright in the good time coming that to be studied will be economy and efficiency—from the side of the profession, physiology (normal and morbid); from the side of the clinician and the public, the efficiency of each cell of the body to maintain for itself and for the body as a whole a dynamic potentiality which will materially and with certainty aid Nature in her great work for the prolongation of life.

Medicine is a science and is becoming more scientific. The healing art we practise is a personal matter and will always be subject to the personal equation. Through inheritance and evolution man is and will be an animal appealed to through his senses, who loves to be humbugged, who has some kind of religion, and who will ever and anon be speculative.

The religion of the true physician is the purest, truest and most untheological of all the Christianities. The physician himself lives and acts more on the lines of the Divinity than any one of another class. He is by the education of his life and by nature of his profession best able to understand man and the humanities. Why should he then be taught in our colleges to treat the *disease?* Why should he not be taught that the great physicians, Hippocrates and Sydenham, treated the patient that the patient might thereby better cure himself, for disease is Nature's fight, and to disturb Nature is to protect rather than lessen.

Man to-day is essentially what he was in the early ages. He who recognizes this and in the recognition practises the art of healing not through Galenic therapy alone, but through an appeal properly guided to the religious man and through an expression of philosophy will lighten man's intelligence and through a proper, careful dignity lead the patient to believe in a physician's second sight.

Can we not appreciate the stubborn facts that medicine through all these ages has been demonstrating the frailties of the human mind, that all the qualities imputed to the serpent have traveled down through the history of medicine and to the present day and that we are still biased by personal speculations, by unfortunate deification of therapeutic agents, and by undue willingness to employ the mystical?

From all this there is but one way out. All our medical colleges should have lectures by competent professors in mental philosophy, whose teachings shall be the physician's attitude toward man and the profession, also lectures by some divine with big brains, not a theologian but one who comprehends man's deeper nature and can explain it. Instead of the Galenicals let us teach the physician, the nurse, and the public the great value of body efficiency and how best to obtain it, and when this has been accomplished it can be said that the healing art has come into its own.

280 Montgomery Street.

## NERVE INJURIES.*

By CHARLES G. LEVISON, M.D.,

SAN FRANCISCO, CALIFORNIA.

FELLOW OF THE AMERICAN COLLEGE OF SURGEONS; VISITING SURGEON TO THE MOUNT ZION HOSPITAL; CHIEF OF THE SURGICAL SERVICE OF THE SAN FRANCISCO POLYCLINIC AND POST-GRADUATE MEDICAL SCHOOL; MEMBER OF THE ASSOCIATION FRANCAISE DE CHIRURGIE, FRANCE.

The period at which nerves commence to exhibit a return of function is uncertain and laboratory statistics are not available, for in practice the trauma plays a rôle that can in no wise be estimated. Experiments give results that are fairly constant but it is easy to appreciate that there are other factors involved in the nature of an injury, so that the prognosis in general can be determined only by a consideration of personal experience as well as a careful study of published cases. The subject of nerve regeneration has been carefully investigated and much has been written about it, but nevertheless there still remains a wide divergence of opinion regarding the process of repair.

According to Murphy†, "The adherents to the theory of central regeneration, Waldeyer and His for example, hold that after division of a nerve a new axis cylinder grows downward into the degenerated peripheral nerve, replacing that which has undergone degeneration.

*Read before the San Francisco County Medical Society, August, 1913.

†*Surgery, Gynecology, and Obstetrics*, April, 1907.

"The neuron theory is based upon the following data: (1) The nervous system consists of innumerable and anatomical independent neurons which are in juxtaposition. (2) An axone is an embryological outgrowth of a nerve cell. (3) The various neurons are anatomically independent and there is no anastomosis of the arborization which terminates in end knots. (4) The axis cylinder separated from its trophic center degenerates but the degeneration does not involve the neighboring neurons. The opponents of the neuron theory hold: (1) That contiguous cells exist only in the embryo and lower animals. (2) That the knots of the arborizations described in support of the 'Central School' are claimed to be artegacts. (3) Clinical experience shows that peripheral regeneration which is quite independent of the central nervous system is possible; in other words, the cells in the anterior horns and spinal ganglia are not necessarily the trophic cells of the axis cylinder. (4) The axis cylinders are not the result of the outgrowth of cells of the nervous system, but arise independently in the periphery from chains of cells which ultimately represent the sheath of Schwann or neurilemma and which only secondarily become united to the central cells.

"The theory of the 'Central School' assumes that regeneration takes place only after degeneration is complete while the 'Peripheral School' holds that regeneration is independent of degeneration. The latter views are the result of histological investigation. When a nerve is divided the peripheral part develops a bulbous end which is due to a curling back of the fibres upon themselves; the neurilemma cells produce small islands of axis cylinders and medullary sheaths; these elongate and place themselves alongside of each other, become fused and eventually form long fibres that unite with those above. In the distal part of a divided nerve which has been united to the proximal, the neurilemma cells are arranged longitudinally and are separated by connective tissue; the *neurilemma* cells are the cells upon which the regeneration of nerves depend."

It is now generally conceded that when a nerve is divided and the axons are brought in terminal contact without intervening connective tissue, restoration of function will practically always occur. The element of time between section and subsequent union of the nerve does not seem to influence the ultimate outcome if all of the indications of the operation have been fulfilled. These indications are as follows: (1) There should be no traction or pressure upon the divided ends of the nerve. (2) The bulbous part of the proximal end must be removed so that the axons project with the appearance of tiny bristles or fibrils which is the sign that all of the connective tissue which interferes with healing has been removed. The same must be done with the distal end. (3) The suture of the connective tissue sheath which brings both ends in terminal approximation should not pass through the nerve proper as is indicated in most treatises on surgery. Murphy speaks of this suture as a "paraneural" suture. (4) The place of union should be surrounded by a layer of fat or muscle; I have employed vaseline, silver leaf, and gutta percha tissue with fair satisfaction, but fat or muscle is probably better, the object being to prevent scar tissue formation and its consequent contraction which produces pressure atrophy with its interference in the transmission of nerve impulses. Dr. A. A. Berg of Mount Sinai Hospital informed me in a recent conversation that he was employing veins with good results to envelop the nerve anastomosis. If the latter procedure works out practically it has many obvious advantages. (5) Muscles must be supported and over-corrected to prevent contractures.

As stated above, all information in connection with the prognosis must be based upon published cases or personal observations and for this reason the following histories are presented.

Case I.—The patient was injured by an exploding gas grate; he had an incised wound below the head of the left fibula. Examination revealed a fracture of the head of this bone and a complete paralysis of all of the extensor muscles of the foot as well as the peroneal muscles. The diagnosis of an injury and probable division of the external popliteal nerve was made. Operation was performed the following day and a division of the anterior tibial nerve was found; this was sutured; the muscular cutaneous nerve was almost but not quite divided; this was also sutured. One year later there was a return of function of all of the muscles with the exception of the extensor longus pollicis. The patient had to lift his foot with a stepping gait when walking on account of a dropping of the great toe. One year later which was two years following the injury, return of function of this muscle is not yet complete but the condition is slowly improving.

Case II.—The patient fell from a stepladder while cleaning gas globes; the globe that she held on her arm broke and made a deep incised wound over the inner posterior third of the forearm; she had the characteristic picture of ulnar paralysis; anesthesia and paralysis of the small finger and the ulnar half of the ring finger; hyper-extension of the small and ring fingers due to a paralysis of the outer head of the flexor prof. digit, and paralysis of the adductors of the thumb. Operation revealed a complete division of the ulnar nerve which was sutured. Ten months later there was a restoration of function of all of the muscles that had been paralyzed excepting the adductor pollicis; after two years the patient had difficulty holding her fork while eating, and after five years while adduction is much stronger, the thumb still remains quite weak.

Case III.—Patient fractured his arm at its lower third; he had a drop wrist and a paralysis of the supinator longus and extensor carpi radialis; operation four weeks later revealed a compression of the nerve by a sequestrum; the sequestrum was replaced and the bone plated; three months later some motion was observed in the supinator group; four months later he had 20° of flexion in his hand; nine months following the injury there was a complete return of function in all of the muscles.

Case IV.—Patient was run over by an automobile March 22, 1913, which produced a fracture of the head of the fibula; following the injury he had a drop foot without sensory change. Operation performed two months subsequent to the injury revealed the nerve drawn tightly over the fractured head of the fibula; the lower part of the nerve was thin, flabby and fatty in appearance while the upper extremity was pinkish and normal in appearance. The end of the bone was chiseled off and the tension of the nerve was relieved. One week later the patient commenced to move his toes slightly and one month later flexion of the foot was evident. Three months later the foot is stronger but flexion is still imperfect. October 27, 1913.—Abduction is complete; the flexors of the foot have not shown any improvement since the last examination.

Case V.—The patient, a boy of six years, was run over by a wagon August 5, 1912, which produced a compound fracture of the upper third of the femur together with an injury to the sciatic nerve below the point of injury. Examination showed a complete sensory and motor paralysis of all of the muscles of the leg and foot; the patient had a drop foot and the question of the flexion of the leg upon the thigh was not possible to determine; there was no sensation whatever in the leg below the knee, although the patient had slight sensation on the inner side of the great toe and the dorsum of the foot which was probably due to the internal saphenous nerve. No attempt was made to determine whether the nerve was severed at the time of the injury on account of a compound fracture that

was present and it was felt advisable to await developments. November 4, 1912.—There was some attempt at adduction of the foot due to a contraction of the posterior tibial muscle; movement of the toes was not possible; a faradic current produced no contraction whatever. December 26, 1912.—There is more sensation at the region of the internal malleolus, although anesthesia is marked all over the foot; there is some sensation in front of the knee below the patella; the foot, however, is quite cold. January 1, 1913.—The surface temperature of the leg is much improved; the foot, however, up to the middle of the leg is cold. February 5, 1913.—The entire foot is warm having the full body temperature; the foot upon contraction is markedly inverted showing the muscles innervated by the posterior tibial nerve to be very active, while those muscles of the peroneal group and the flexors of the foot are practically inactive. April 1, 1913.—The patient has decided flexor movements in his toes, which were never there before; the gastrocnemius muscle contracts well and there has been a complete return of function in all of the flexor muscles of the foot. August 1, 1913.—There has been a complete return of function of all of the muscles of the entire leg and foot. October 15, 1913.—The patient is practically well.

Case VI.—The history of this patient is of more than passing interest. He first noticed a lump on his cheek at the angle of the jaw that was due to a dropping of the facial muscles; he then recognized that one side of his face was paralyzed. After fifteen months the patient consulted me; this paralysis was still present; at this time he complained of pain in the mastoid region which was agonizing when his head was rubbed by a barber. Examination showed a complete peripheral paralysis. He was unable to wrinkle his forehead; taste perception in the anterior part of his tongue was less acute than on the corresponding side. Mastoid very sensitive to pressure; this is probably periosteal tenderness. Middle ear examined by a specialist is found normal; scars and thickening over the tibia present. There was a history of lues present, also a positive Wassermann reaction, which suggested that the trouble might be of luetic origin and appropriate treatment was instituted. He was given two injections of salvarsan which relieved the periosteal pain at once and with the aid of more treatment the paralysis gradually subsided so that after one year, as seen by photographs, the condition was greatly improved; that muscle which has not responded to treatment altogether has been the occipito frontalis. The diagnosis here was evidently a gumma producing pressure on the facial. A most unusual condition.

There have been several occasions where the branch of the facial that dips down below the horizontal ramus of the jaw and which goes to the levator labii inferioris has been injured in the course of gland operations of the neck; following the operation in these cases the deformity has been marked, but in each instance regeneration has been complete.

350 Post Street.

## A CASE OF SYPHILIS CURED APPARENTLY BY ACCIDENT.

By J. BAYARD CLARK, M.D.,
NEW YORK.
ASSISTANT GENITOURINARY SURGEON, BELLEVUE HOSPITAL.

This extraordinary occurrence seems to me to be worthy of reporting, as the simple facts of the case furnish suggestions on the therapeutics of syphilis which have not to my knowledge been previously pursued by the medical mind:

April 1, 1905, an Irishman, M. C., a robust mechanic, of temperate habits, aged 27, came to me with the following history: Two months previously he had noticed a sore on the penis, which appeared about two weeks after a sexual exposure, and for which he sought no medical attention; but the development of a rash on his body and a sore throat had caused him to seek medical advice. The physical examination showed the entire body to be covered with a perfectly typical macular rash. There was a general adenitis and a characteristic pharyngitis. The diagnosis of syphilis was unfalteringly made.

The reader will note that the date was just previous to the announcement of Schaudinn and Hoffmann's discovery of the *Spirocheta pallida*. It must also be borne in mind that the serum reaction of Wassermann was, at that time, unknown, so of necessity the diagnosis had only the support of the clinical evidence, but this evidence was so frank that it left no doubt as to the certainty of the case being one of syphilis.

The patient was started on the inunction plan of treatment and given a prescription for 2 ounces of unguentum hydrargyri with directions as to how he should use it, in proportions of about 1 dram to a rubbing. This explanation had evidently missed the mark, as he returned in four days time, having used the entire 2 ounces in the space of four rubbings, and rubbed it in over the entire body. By April 7 there was a decided diminution of the macular rash, and as he showed no toxic effects, he was again started on inunctions, and made to understand how to proportion the amount used at each rubbing and told to use it this time but every other day.

This treatment was continued until May 3, which will be noticed was a period of just one month's duration. The patient at that time left the city. From then until May 6, 1911, just six years after, I heard or saw nothing of him. When he returned to me he stated that during that period he had no treatment or care of any kind; that he felt perfectly well and had seen no signs of the disease. Having heard about the new treatment of syphilis with salvarsan, he thought perhaps it might be well to have an injection of this new remedy. He looked and seemed to me to be entirely well and healthy, and a careful search revealed no signs of the old infection, so I advised him before considering any further treatment to allow me to make a blood test. The Wassermann reaction proved to be entirely negative. I therefore told him I saw no necessity for treatment, but suggested his coming in in a few days' time to check up the blood test by another. I saw nothing of him after that time until December 15, 1912, when he came in suffering with a furunculosis, which he thought might be syphilis. A Wassermann reaction again proved negative. May 13, 1913, or about six months subsequent to his last visit, he presented himself again in order to have, as had been previously requested, another blood test made. This again was entirely negative.

There are but two conclusions possible to be drawn drom this case, assuming that the diagnosis was correct and that the Wassermann tests can be depended upon. The first and unimportant conclusion was that this man was one of those persons in whom the natural resistance of the body is sufficient to overcome and cure the disease. The second conclusion forms the basis for a rather fascinating speculation, to which we may turn in the form of the following questions:

Is not the amount of mercury which the body can endure, barring the corrosive salts, very much greater than is commonly supposed? Is it not within the province of reasonable speculation that we may come as near to a therapic sterilans magna with mercury as with an arsenical preparation?

616 Madison Avenue.

## STREPTOCOCCIC INFECTION OF THE CERVIX UTERI.

By E. A. PETERSON, M.D.,

MOBILE, ALA.

THE following case is of unusual interest, because of the paucity of the literature on the subject, either in the journals, or in the text books, as well as because of the intense suffering which it may produce and the length of time during which it may prevail unless the proper treatment is instituted. It may be possible that any portion of the female generative tract may become the site of a primary infection, which may confine itself to this particular location, but this case is the only one that has come to my notice:

CASE.—The patient, a young woman eighteen years of age, unmarried, came to me in the early part of January, 1913, suffering from an intense infection of the vulva. She was well nourished, belonged to the better classes of society, had never had any severe illness other than an attack of appendicitis, for which she had been successfully operated upon three years before. She had no abdominal or pelvic tenderness, was regular in her menstrual life, except for slight pains the first day of her menstruation, and up to a few months before this time had never had the slightest trace of leucorrhea. At this time she had taken up her residence with a sister who had been operated upon for pus-tubes, and who still had an offensive leucorrhea, and she slept with two nieces, nearly her age, who also suffered with leucorrhea, and to these she attributed the source of her infection. Examination of the vulva showed an intense erysipeloid inflammation involving entirely the external genitals and the surrounding skin for a distance of one inch. This was accompanied by itching and burning, which became almost unbearable especially when the clothes were allowed to touch the parts. Believing that I had a case of pruritis vulvæ to contend with I ordered the patient to remain in bed, and general antiphlogistic treatment was instituted, with a douche for the leucorrhea. An intact hymen precluded a vaginal examination at this time. A week's treatment of this kind sufficed to overcome all external symptoms, except the leucorrhea. Two weeks later, however, the same condition appeared again in spite of the continuation of antiseptic douches. Three weeks later, while in another city, the patient suffered another attack of the same kind, which confined her to the house for two weeks, during which period she was under the treatment of another physician. On March 16 she had another attack. She was then taken to the sanatorium, a vaginal examination was made, and it was found that the cervix on almost all of its vaginal extent was the site of a fiery red erysipelatous eruption. It appeared as if the vaginal mucosa had been carefully dissected from this portion. The line of demarcation between the inflamed surface and the very pale vaginal mucous membrane was strikingly distinct and no other inflamed area could be discovered in the vagina. The cervix was thoroughly cauterized with carbolic acid and the cervix was dilated under ether anesthesia, but the uterine mucosa presented as healthy an appearance as the vaginal. About one month's local treatment consisting of the daily application of argyrol tampons around the denuded area, sufficed for its healing. Boroglyceride and carbolic acid applications were also used, but these did not seem to have anything like the effect of the argyrol. It was interesting to watch the daily growth of mucosa over the raw surface, this taking place in offshoots from the healthy mucosa, with the filling in of the interspaces. The patient has had no further trouble for nearly a year. Bacteriological examination showed an immense number of streptococci, mostly in chains of from four to six organisms. The examination of swabs from the uterine mucosa was negative.

The case described must not be confounded with the condition commonly known as cervical erosions, as in this condition we have an eversion of the endocervical mucosa, and it is this portion of the tissue that is inflamed, while in the case presented, the inflammation was confined to the vaginal portion of the mucosa. Cervical erosions are confined, I believe, to the cervices of women who have borne children, and who have had a slight tear of the cervix, thus allowing a prolapse of the endometrium of the cervix, with its consequent inflammation.

It would be interesting to know what percentage of girls suffering from leucorrhea, of which we see numbers, are affected in a similar way. This case illustrates as fully as it can, the futility of treating with douches the symptom ordinarily known as leucorrhea, or "whites," without a vaginal examination, and the determination of the cause of the condition.

BIENVILLE HOTEL.

---

**Pneumococcal Infection of the Pharynx and Larynx.**—P. Turner and W. M. Mollison report the case of a man aged 23, who was admitted to Guy's Hospital in April last, on account of tenseness and a brawny swelling in the right submaxillary region; this was incised under an anesthetic. During the course of the operation the patient developed so much dyspnea as to necessitate a laryngotomy; the tube was removed in a day or two and the patient made a fair recovery, though he had all the time some swelling about the pharynx and tonsils. In July the patient was readmitted with increasing dyspnea. Tracheotomy had to be performed and ever since the tube has been worn. Examination of the larynx before readmission had shown edema of the epiglottis and arytenoid regions. In August a further examination of the patient was made under an anesthetic; it was found that the soft palate and uvula were edematous and the tonsils large and ragged. The right tonsil contained a cavity into which the tip of the finger could be introduced; it was enucleated, and on bacteriological examination a pure culture of pneumococcus was obtained. The edematous epiglottis was punctured and cultures taken from the serum were obtained; these cultures showed the pneumococcus and the *Bacillus catarrhalis*. The patient still has much swelling about the upper aperture of the larynx, and is unable to dispense with the tracheotomy tube. The temperature has varied from 99° to 97° F., except for two days following the tracheotomy. Two weeks previously the patient had a quinsy on the left side.—*Proceedings of the Royal Society of Medicine.*

**A Case of Mesenteric Cyst Simulating an Intussusception.**—P. Turner and H. Tipping report the case of a male infant aged four months who was admitted to Guy's Hospital for passage of blood from the anus. Until a week before admission the child had been perfectly well, but during this week he had been slightly irritable, had not been sleeping as well as usual, and had had several "crying fits." On the morning of admission he did not have a good stool. In the evening blood was passed and he was taken to the hospital. On admission the child did not appear to be in pain, and nothing could be felt on abdominal palpation; a rectal examination, however, showed the presence of recent blood. An anesthetic was given and then a small movable lump was felt just below and to the right of the umbilicus. A diagnosis of intussusception was made and the abdomen was at once opened. The lump was found to be a tense cyst, about one inch in diameter, situated in the mesentery in the angle between the ileum and the colon. It bulged into both these portions of the intestine, causing obstruction at the ileocecal valve. An attempt was made to remove the cyst, but though it was easily separated from the mesentery its walls appeared to be absolutely incorporated with the wall of the ileum and cecum. As it seemed certain that any further attempt at removal would result in damage to the bowel, the cyst was incised and a quantity of white, odorless, glairy fluid was evacuated. There was no communication between the cavity of the cyst and the bowel. The greater part of the cyst wall was cut away and the edges were then sewn to the parietal peritoneum. The cavity was drained and the rest of the wound closed. The first stool after the operation contained blood, but afterward the bowels acted regularly and the stools were normal. Mucoid material discharged from the wound for some time, but this eventually healed. Since then, on two occasions, incisions were required to allow of the escape of mucoid material. A section of the cyst wall showed a structure closely resembling small intestine.—*Proceedings of the Royal Society of Medicine.*

## THE CLINICAL SIGNIFICANCE OF THE VITAMINES.

It is a little over two years since Casimir Funk announced the discovery of a class of chemical compounds to which he gave the name the "vitamines." He isolated these substances from rice polishings, in which they are present in the minute proportion of not more than one-tenth of a gram to a kilogram of rice. The clinical importance of this discovery resides in the fact that the administration of a small amount of the vitamines cures the polyneuritis of birds, a disease which is apparently identical with human beriberi. In his earlier experiments Funk found that the neuritis-preventing principle of rice-polishings is an organic base, which is completely precipitated by phosphotungstic acid and by silver nitrate and baryta. It crystallizes in colorless needles which melt at 233°, and appears to have the formula $C_{11}H_{20}N_2O_7$. Of this substance 0.02 gram effects a rapid cure of polyneuritis in pigeons.

The vitamines are present in other substances besides rice polishings. Eykman showed that they can be extracted from yeast by means of alcohol. But Funk showed that a greater portion of the vitamines is present in the yeast in a combined state from which it cannot be extracted by means of prolonged boiling with alcohol. Employing elaborate methods of extraction, Funk succeeded in isolating the neuritis-preventing principle in its pure state from yeast, and found that 2 to 4 centigrams of the active principle are sufficient to cure polyneuritis in pigeons. The name "vitamine" was suggested for this substance, minute quantities of which are essential in the diet of man and other animals. The vitamines are regarded as bases probably belonging to the pyramidine group, and a constituent of nucleic acid. The vitamines have also been isolated from milk and from brain tissue, and a neuritis-preventing substance probably identical with or related to the vitamines has been extracted from lime-juice.

The vitamines are destroyed by a temperature of 120° centigrade, and also by prolonged boiling. The importance of this fact should be considered in connection with what is known regarding the etiology not only of beriberi but also of scurvy and infantile scurvy, and possibly of rickets. The absence from the diet of fresh vegetables or of fruit juices, both of which are known to contain the essential vitamines, has for a long time been recognized as the cause of scurvy. Likewise the use of boiled milk as an exclusive diet for infants has been regarded as the important factor in the etiology of infantile scorbutus. If this theory is correct, it can readily be understood how boiling, by destroying the vitamines, is the factor that is chiefly at fault in the production of this condition. If boiling destroys the vitamines, however, it is not easy to understand why the use of unpolished rice, which is boiled equally with polished rice before being eaten, should prevent beriberi. Within recent years the use of fresh vegetables or of vegetable juices has been extolled in the treatment of diseases other than scurvy, particularly in tuberculosis.

It is probable that the vitamines include a series of substances differing in certain respects from one another. Indeed Vedder in his recent work on beriberi suggests that the wet and the dry forms of this disease may be caused by a deficiency of one or another vitamine, the lack of one of which causes prostration, heart failure, and dropsy, while that of another causes neuritis.

The process of isolating the vitamines from the pericarp of rice or from other foodstuffs is a laborious one, and large quantities of the substance must be handled before even an appreciable amount of the active principle can be obtained. It is to be hoped that other sources for the vitamines may be discovered, in order that they may be available for therapeutic purposes in beriberi and scurvy and possibly in other diseases accompanied by disturbances of nutrition.

## OPERATIVE TREATMENT OF MALIGNANT DISEASE OF THE LARGE INTESTINE.

The large intestine is more frequently the seat of malignant disease than any of the internal organs, and from its situation is not easily amenable to treatment. Radium and the *x*-rays are not available for treatment of cancer of the large intestine and thus the only possible remedial or curative methods are those of surgery. Provided the disease is diagnosed at an early stage, surgical measures in the hands of the experienced operator frequently show satisfactory results.

At the International Congress of Medicine held in London during the past summer Dr. Raffaele Bastianelli of Rome read a paper on the operative treatment of malignant disease of the large intestine in which he gave the following table, the cases having been collected from the data of a few surgeons of wide experience: Total number of cases operated on more than three years ago, 239; operative cures, 140; alive and well three years after, 68, or 42.8 per cent. of the survivors from the operation, or 28.8 per cent. of all operated upon.

According to Bastianelli the location of the tumor is of great importance. It seems that those of the cecum give about double the percentage of permanent cures as compared with those of the left side, and this may be due not only to the prevail-

ing adenomatous type of the first, but also to the possibility of an earlier discovery and a more extensive operation. Bastianelli ends by saying: "The percentage of definite cures given above is by no means a full expression of the truth. If we consider that in every set of statistics cases are reported dying from recurrence after three, four, five, and six years, there is good reason to doubt the value of some optimistic views. If we consider that at most half of all large bowel tumors are not operable, and that 75 or somewhat more per cent. of the other half survive the operation, and of these only about 43 per cent. are well after three years, and that not a few die from recurrence after three years, it is easy to see that at the present stage of our diagnostic and therapeutic resources we can save only a very small proportion of all the people suffering from this disease, perhaps 15 per cent. or something like that. An early diagnosis and a small operative mortality will increase immensely our therapeutic power and the recent progress in both lines makes it possible to hope for a great improvement in the statistics of the next decennium."

An early diagnosis of malignant disease of the large intestine and a lower operative mortality doubtless go hand in hand. If the malady can be diagnosed at a sufficiently early stage naturally the operation should be more successful and more complete in every way. Unfortunately, the early diagnosis is, as Bastianelli says, a rare and doubtful possibility. He believes that Boas is within certain limits right when he remarks "the stage in which a really early diagnosis would be very hopeful is for the patient and for us beyond our means of investigation." The most hopeful feature of the situation is that methods of diagnosis are rapidly improving. Proctosigmoidoscopy and *x*-ray bismuth examinations already have rendered possible the detection of malignant disease of the large intestine at a stage in which operative measures hold out good hopes for a curative result. As our means of diagnosis improve so will the future be more hopeful.

## CEREBRAL POSTDIPHTHERITIC PARALYSIS.

A GREAT deal has been written on the subject of cerebral paralysis following the various acute infectious diseases. There has been abundant postmortem evidence that the paralysis is due in some of these cases to cerebral embolism or thrombosis and in other cases to encephalitis. In diphtheria the occurrence of paralysis is particularly common and has been attributed as a rule to a toxic peripheral neuritis. Nevertheless there has arisen a conception that many of the cases of postdiphtheritic paralysis are the result of changes in the central nervous system, either of an inflammatory or of a degenerative nature. As in the case of poliomyelitis, one is justified in assuming in diphtheria a generalized intoxication of the entire nervous system, an intoxication which may be so mild as to give no outward symptoms or so severe as to cause more or less extensive paralysis or sudden death. More than forty years ago McDonald pointed out that in a large percentage of cases of diphtheria there is an absence of the knee-jerk. This indicates a certain degree of involvement of the nerve paths leading into or from the spinal cord or of the ganglia and tracts of the spinal cord itself. Cases of postdiphtheritic paralysis resembling Landry's paralysis, other cases resembling hemiplegia, and still other cases resembling acute bulbar paralysis have been described.

The latest contribution to this subject has been made by A. L. Dynkin in the *Jahrbuch für Kinderheilkunde*, July, 1913. He finds that the cerebral paralyses occur only after the severe forms of diphtheria. In these cases one may find a history of cardiac weakness, as evidenced by arrhythmia, increased dullness, and murmurs. Cerebral paralyses in the form of hemiplegia occur from two to five, and most frequently from three to four weeks after the beginning of the acute illness. Coincident with the hemiplegia one may frequently observe a paresis of the facial and hypoglossal nerves as well as aphasia. In many cases cerebral paralyses are combined with the peripheral ones, such as paralysis of the soft palate and of the muscles of accommodation, the loss of the knee reflex, and the loss of control of the sphincters. The outcome is generally fatal, occurring as the result of heart paralysis, or after a longer or shorter time, usually one month after the beginning of the original attack, as a result of intercurrent complications. In many cases recovery ensues with a return of power to the limbs and a restoration of speech. The complete and rapid disappearance of all cerebral symptoms is, however, seldom observed. The cause of postdiphtheritic paralysis is in the majority of cases embolism resulting from cardiac thrombosis or less frequently it may be thrombosis of the cerebral blood-vessels. It is quite doubtful whether hemorrhage into the brain occurs in partly uncomplicated cases. The author believes that no case has yet been reported in which the paralysis was the result of an encephalitis. Since, however, the literature contains undoubted cases of encephalitis which are not associated with hemiplegia, the author believes that it is not unlikely that such an association between encephalitis and hemiplegia may occasionally occur after diphtheria.

## NATIONAL INSURANCE IN ENGLAND AND THE HOSPITALS.

NATIONAL insurance has been on trial in England for a sufficiently long period now to allow of a certain amount of judgment as to its effect on the medical profession. On the whole, from the pecuniary standpoint, at any rate, medical men do not seem to have suffered as a result of the passing of the Insurance Act. Indeed, it is stated in some quarters to have benefited medical men generally. If Mr. Lloyd George is to be believed it has been already of incalculable benefit to the profession. However, the dicta of professional politicians in no country can be taken altogether seriously, and the Insurance Act in England must be on trial

for a much longer time ere a final judgment can be passed on it. The German Insurance Act—which has had a far more extended trial than the English act and which in some respects is more advantageous to the medical man—is by no means popular with the medical profession of Germany.

The effect of the law on the hospitals of England is problematical. The outstanding feature of the English hospital system is its voluntary character and it would appear that the act cannot but have a profound influence, probably a disturbing influence, on the system. As is pointed out by Dr. Donald Mackintosh of Glasgow in a paper read at Boston in August, 1913, and published in the *Canadian Journal of Preventive Medicine and Sociology* for January and February, 1914, the National Insurance Act in England was drafted apparently on the understanding that these conditions would continue and this has proved to be the case so far. The act takes cognizance of hospitals in only two clauses, one of which places the hospitals at a manifest disadvantage and the other makes it lawful for an approved society to grant such subscriptions or donations as it may think fit to hospitals, dispensaries, or other charitable institutions. As a matter of fact, the act strikes at the root of the whole voluntary principle, and it may not be long before those responsible for the management of English hospitals will clash with government officials. Mr. Lloyd George is naturally optimistic, but it is likely that he would not concern himself greatly if the voluntary system were to be abandoned. His chief adviser in the drafting of the Insurance Act was a retired medical man of distinctly socialistic tendencies, and the leaning of the political party with which he is allied appears to be toward nationalization of the medical service of England and the hospitals. The National Insurance Act looks as if it were intended as the thin end of the wedge. Medical men in England have no political organization and consequently their political power is a negligible quantity. The Insurance Act was not meant to benefit the medical profession, but was launched as a means of gaining popularity with the masses, and with regard to the hospitals of England the signs assuredly seem to point to the abolition of the existing system.

### Noma.

The gradual disappearance of this disease from literature has led to speculations as to the noma of prescientific days, which was believed to refer to a gangrenous termination of a number of local affections. Von Brunns once collected notes of over 400 cases, and in the great majority some infectious disease, notably measles, had acted as a forerunner. The affection is very rare in both nurslings and adults. Quite often the child seemed in good condition when attacked. At a recent meeting of the Berlin Laryngological Society (*Berliner klinische Wochenschrift*, 1914, No. 4) Claus reported a case occurring in a woman with chronic polyarthritis, including a heart lesion. Recently acute endocarditis developed, with hemorrhages into the conjunctivæ. Soon afterwards the right cheek was seen to be swollen. On the inner aspect a gangrenous bleb was found in the typical location, *i.e.* midway between the opening of Steno's duct and the angle of the mouth. The outward swelling extended as high up as the eye and zygomatic process. Next a small bleb appeared on the outside of the cheek. The odor was horrible. Before the disease had progressed far, death occurred from a complication—aspiration pneumonia. The upper and lower maxillary bones had been denuded and the pterygoid muscles were exposed. The affection appeared to be due to a mixture of infections in which Vincent's bacillus and spirocheta were prominent. In the present instances the forerunner was evidently rheumatism, which first caused an exacerbation of the old cardiac lesion.

### Contraindications to Vaccination.

As a rule cases in which vaccination is followed by untoward effects, even when all precautions are used, exhibit certain peculiarities which, if carefully investigated ought to cause a postponement of the operation. Groth in a paper published in the *Münchener medizinische Wochenschrift*, February 3, restricts the subject to children. Even the law forbids revaccination of children with such acute or chronic disease as interferes with nutrition. Irrespective of this provision of the law Groth gives the following conditions temporarily rendering the case unsuitable for vaccination: severe acute diseases, mild disturbances of nutrition, bronchitis, open tuberculosis, severe rickets, the exudative diathesis (as expressed in various forms of eczema), impetigo contagiosa, etc. These exceptions are made in part for moral effect, for in such children their infirmities are constantly becoming better or worse and an exacerbation is readily set down to vaccination, which indeed sometimes seems to cause latent affections to become manifest.

## News of the Week.

**Death Rate Falls.**—For the week ending March 14 the death rate in New York City was 15.93 per 1,000 of population, representing a total of 1,705 deaths or 215 less than during the same week of 1913 when the death rate was 17.94. For the preceding week of this year the death rate was 18.28, and the total number of deaths 1,957. For the first eleven weeks of 1914 the death rate was 15.45, a decrease of 0.34 from that for the corresponding period of 1913.

**Montefiore Home.**—The twenty-ninth annual report of the Montefiore Home for Chronic Invalids, New York, shows that 1,083 patients were cared for during the past year, of whom 472 remained under treatment at the close of the year. With the exception of forty-three, all of these were treated free of charge. The new building on Gun Hill road and Jerome avenue, to which the home was recently moved, was erected at a cost of $1,965,000 and with the country home for tuberculosis patients has a capacity of 700 beds. Twenty-nine years ago when the home was established at Avenue A and Eighty-fourth street it provided accommodation for twenty-six patients.

**Christian Scientists Score.**—The New York Senate on March 20 passed the McClelland-Thorn bill which legalizes Christian Science healing by amending the Medical Practice Act so as to exempt from its provisions "any person who ministers to or treats the sick or suffering by mental or spiritual

means without the use of drugs or any material remedy."

**Personals.**—Prof. T. Mitchell Prudden of New York has been appointed by Governor Glynn a member of the New York State Public Health Council.

Dr. Thomas Darlington of New York has been appointed as a member of the commission to administer the law under the Workmen's Compensation bill which was signed by Governor Glynn on March 16.

Dr. Samuel Graham Underhill of Groton, Mass., has been elected superintendent of the Lynn Hospital, Lynn, Mass.

Dr. Forrest C. Tyson of Bangor, Me., will shortly take up his new duties as superintendent of the Augusta Hospital, Augusta.

Dr. Robert G. Devereux of Philadelphia has been appointed assistant medical inspector to the Philadelphia Board of Health in succession to Dr. A. C. Marshall resigned.

Drs. Wilfred W. Hawke and Alfred J. Ostheimer of Philadelphia have been appointed committing physicians to the Psychopathic Ward of the Philadelphia General Hospital.

Dr. Martin E. Rehfuss has returned from Paris and resumed practice in Philadelphia.

Dr. William H. Walsh has been appointed chief resident physician to the Philadelphia General Hospital in succession to Dr. Henry Sykes deceased.

**Canal Zone Appointments.**—The details of officers of the army and navy to positions in the permanent government of the Panama Canal were announced at the War Department, Washington, on March 20. The appointments in the Health Department are as follows: Chief Health Officer, Lieut.-Col. Charles F. Mason, Medical Corps, U. S. Army; Superintendent of Hospital, Lieut.-Col. George D. Deshon, Medical Corps, U. S. Army; Chief Officer of the Quarantine Division, Passed Assistant Surgeon Marshall C. Guthrie, U. S. Bureau of Public Health.

**Health of the Canal Zone.**—During the month of January, 1914, the total number of deaths from all causes among the employees of the Isthmian Canal Commission was 33, of which 20 were due to disease and 13 to violence, making a total annual average death rate per 1,000 of 8.03. The annual average death rate per 1,000 in the cities of Panama and Colon and the Canal Zone, including both employees and civil population for the month was 25.94, a considerable increase over last year and over 1912 when the record for the month was 17.67. Among employees, deaths from the principal diseases during the month were as follows: Dysentery, 1; lobar pneumonia, 4; malarial fever, 1; tuberculosis, 7. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the month.

**Dr. Rotch's Will.**—By the will of Prof. Thomas Morgan Rotch of the Harvard Medical School, who died recently, the largest part of his estate will, on the death of his wife, go to the Infants' Hospital, Boston, to be used in connection with the Thomas Morgan Rotch, Jr., Memorial Building, which was erected not long ago by friends of Professor Rotch in memory of his son. A portion of the income of the estate may be paid, at the discretion of the trustees, to the Harvard Medical School, to be used for the department of pediatrics. The value of the estate has not been determined.

**Nurses Graduate.**—At the graduation exercises of the New York Hospital Training School for Nurses on March 18, diplomas were bestowed on thirty-four nurses by Mr. George L. Rives, president of the hospital.

**Public Meetings on Cancer.**—The American Society for the Control of Cancer has arranged for two public meetings in connection with the congress of the American Surgical Association in New York next month. The first meeting will be held at the Academy of Medicine on Friday evening, April 10, when Dr. William J. Mayo of Rochester, Minn., and Mr. Frederick L. Hoffman of the Prudential Insurance Company, will discuss the problem of cancer and its control; Prof. Francis Carter Wood, Director of the Crocker Special Research Fund of Columbia University, will speak on the effect of radium on malignant growths; and Dr. J. Collins Warren, chairman of the Cancer Commission of Harvard University, will tell of the work being carried on at Harvard. The second meeting will be held on Saturday morning, April 11, at eleven o'clock at the Hudson Theater, and the speaker will be Mr. Frederick L. Hoffman, who will take for his subject "The Menance and Control of Cancer." The public is invited to attend both of these meetings.

**Brooklyn Pathological Society.**—At the meeting of this society, to be held on April 9, Dr. Wm. T. Councilman of the Harvard Medical School will deliver an address on "Glioma." A number of neurologists in Manhattan and Brooklyn have accepted the invitation to discuss this subject.

**The Chi Zeta Chi.**—At the annual meeting of this society held March 5 at the residence of Dr. Leo Petersen the following officers for the ensuing year were elected: Dr. Robert H. M. Dawbarn, *President;* Dr. Evan Evans, *First Vice-President;* Dr. J. E. Donelly, *Second Vice-President;* Dr. C. B. Fluker, *Secretary and Treasurer.* The next meeting will be held at the residence of Dr. Dawbarn, at 8.30 on the first Thursday evening in April.

**Legislation Against Wood Alcohol.**—The Codes Committees of the New York State Senate and Assembly held a joint hearing on March 18 on the Griffin-Thorn bill which prohibits the manufacture and sale of wood alcohol combinations without the poison label. The bill, which was drafted by the New York Committee for the Prevention of Blindness and has the support of a number of influential organizations, prohibits the manufacture or sale of any article of food or drink containing methyl alcohol, or of any preparation or mixture containing methyl alcohol intended for internal use by man; and provides also that no person or corporation shall sell or offer for sale methyl alcohol in any form, or any preparation or mixture containing methyl alcohol, under any name or trademark, unless there be affixed to the bottle or vessel containing the same a conspicuous label bearing the words: "Poison—Likely to Cause Blindness or Death," together with a skull and cross bones, all printed in red ink. Violation of the provisions of the bill is made a misdemeanor.

**Bequests to Charities.**—The German Hospital and St. Catherine's Hospital, Brooklyn, receive $5,000 each by the will of the late Louis Bossert of that city.

By the will of the late Mrs. Mathilda E. Webb of Brooklyn the Long Island College Hospital, the Brooklyn Home for Consumptives, the Brooklyn Hospital, and the House of St. Giles the Cripple receive each one-tenth of an estate estimated at $200,000.

The Presbyterian Hospital, the Knickerbocker Hospital, and the New York Red Cross Hospital, New York, receive $500 each by the will of the late Miss Julia A. Crawford of this city.

By the will of the late Mrs. E. N. Andreas of Brooklyn the sum of $3,000 each is left to the Stony Wold Sanatorium, St. Rose's Free Home for Incurable Cancer, and the New York Medical College and Hospital for Women.

**Medical Society Elections.**—At the thirteenth annual meeting of the Seventh District Medical Society, Georgia, held at Rome on March 11, the following officers were elected for the ensuing year: *President*, Dr. William G. England, Cedartown; *Vice-President*, Dr. J. Hill Hammond, Lafayette; *Secretary*, Dr. William Littell Funkhouser, Rome.

At a meeting of the Milam County, Texas, Medical Society at Cameron on March 10, officers were elected as follows: *President*, Dr. Hiram F. Coulter, Rockdale; *Secretary*, Dr. Green B. Taylor, Cameron.

**The Late Dr. Simpson.**—The following minute was adopted at a meeting of the Medical Board of the Presbyterian Hospital on March 9: "In the death of Dr. William Kelly Simpson, Special Consultant in Laryngology, the Medical Board of the Presbyterian Hospital has suffered an unusual loss. An early graduate of the Hospital, familiar with its men and its history, and embodying in himself its traditions of intelligent, devoted service, Dr. Simpson had served this institution in his earlier years in the Dispensary, more recently as Consulting Otologist and Laryngologist, practically throughout his professional life. On many occasions he was called upon for help in cases not coming strictly within the limits of his official position, but whatever call was made upon him in the name of the Presbyterian Hospital was always answered at once. His willingness to give any service within his power was as notable as the skill and fidelity with which the service was rendered. Even when himself suffering, he gave up his work for others only when compelled to do so. All his service was rendered with a kindliness and a great humor which multiplied its value. For more than thirty years he has given us his best aid. To most of us his genial presence and winning personality had become seemingly essential parts of this institution. In the days before us we shall miss the services of a devoted and skillful surgeon, we shall miss still more our friend.

"As an expression of our appreciation and our sympathy, this minute is directed to be entered in the records of the Board and to be transmitted to the family of our late colleague."

**Obituary Notes.**—Dr. William Bedford Brown of New York, a graduate of the Jefferson Medical College, Philadelphia, in 1889, professor of dermatology in the New York Post-Graduate Medical School, a member of the New York State and County Medical Societies, the Manhattan Dermatological Society, and the Greater New York Medical Society, and dermatologist to the Samaritan Hospital of Brooklyn and the Demilt Dispensary, New York, died on March 9.

Dr. Christopher C. Walker of Gainesville, Tex., a graduate of the Medical Department of the Tulane University of Louisiana, New Orleans, in 1866, died on February 24 at Los Angeles, Cal., where he had gone in search of health, aged 73 years.

Dr. John Laing Leal of Paterson, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1884, a member of the Medical Society of New Jersey and the Passaic County Medical Society, president of the New Jersey State Sanitary Association, and ex-president of the Board of Health of Paterson, died at St. Joseph's Hospital in that city from diabetes on March 13, aged 55 years.

Dr. James Nicholas Butler of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1888, died at his home on March 14, aged 53 years.

Dr. Samuel Schaie of New York, a graduate of the University of Berlin, Germany, in 1875, and a member of the German Medical Society, died suddenly, from heart disease, at his home on March 19, aged 63 years.

Dr. Daniel Simmons of Brooklyn, N. Y., a graduate of the New York Homeopathic Medical College and Hospital in 1873, a member of the American Institute of Homeopathy and the New York State Homeopathic Medical Society, and consulting physician to the Cumberland Street Hospital, Brooklyn, died at his home, on March 18, aged 70 years.

Dr. George Oakley Welshman of Newark, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1895, was instantly killed on March 16, when the automobile which he was driving was struck by an express train at the North Grove street crossing of the Lackawanna Railroad. Dr. Welshman was a member of the American Medical Association and the New Jersey State and Essex County Medical Societies.

Dr. Conrad R. Bready of Philadelphia, Pa., a graduate of the Jefferson Medical College of Philadelphia, in 1880, and a member of the Medical Society of the State of Pennsylvania and the Philadelphia County Medical Society, died at his home, on March 10, aged 54 years.

Dr. Woodward D. Carter of Philadelphia, a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1894, died at his home, on March 18, aged 47 years.

Dr. Henry Sykes, for the past eight years Chief Resident Physician to the Philadelphia General Hospital, died at Jefferson Hospital, on March 19, at the age of 53 years, as the result of carcinoma of the lower jaw, for the relief of which operation had been undertaken. Dr. Sykes was born in Nova Scotia and was graduated from the Medical Department of the University of Pennsylvania in the class of 1884. He subsequently served as resident physician in the University Hospital, Wills Eye Hospital, and the Pennsylvania State Hospital for the Insane at Norristown, and later he became Chief Resident Physician to the Episcopal Hospital at Philadelphia, serving in this latter capacity for eighteen years.

Dr. Charles H. Dwyer of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1883, died at his home, on March 12, aged 67 years.

Dr. Thomas Dyer Henderson of Philadelphia, a graduate of the Medical Department of the University of Pennsylvania, Philadelphia, in 1901, died at the Presbyterian Hospital in that city, from pleurisy, on March 9, aged 36 years.

Dr. William DeHaven Eaches of Phœnixville, Pa., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1894, died at his home on March 11, aged 41 years.

Dr. Henry A. Grim of Allentown, Pa., a graduate of the Medical Department of the University of

Pennsylvania, Philadelphia, in 1855, and a surgeon in the United States Army during the Civil War, for a time chief surgeon to the First Division of the Army of the Potomac, and active in the battles of Antietam, Fredericksburg, and Gettysburg, died at his home, on March 8, aged 82 years.

Dr. William Coe Monroe of Woonsocket, R. I., a graduate of the Bellevue Hospital Medical College, New York, in 1876, health officer of Woonsocket, chief of staff of the Woonsocket Hospital, a member of the Board of Trustees of the Rhode Island State Sanatorium, chairman of the medical board of the Woonsocket Hospital, and a member of the American Medical Association and the Rhode Island and Providence District Medical Societies, died at his home from edema of the lungs, on March 11, aged 64 years.

Dr. James A. Anderson of Lynchburg, Va., a graduate of the University of Virginia, Department of Medicine, Charlottesville, in 1879, and a member of the Medical Society of Virginia and the Lynchburg Academy, died suddenly from acute indigestion on March 13.

Dr. Benjamin Grigsby Copeland of Birmingham, Ala., a graduate of the Jefferson Medical College, Philadelphia, in 1883, professor of surgical anatomy and clinical surgery in the Birmingham Medical College, and a member of the Medical Association of the State of Alabama and the Jefferson County Medical Society, died at his home, after a short illness from tetanus following a slight scratch on the leg, on March 11, aged 53 years.

Dr. Van Buren Potts of Maplesville, Ala., a graduate of the University of Alabama, Medical Department, Mobile, in 1904, and a member of the Medical Association of the State of Alabama and the Chilton County Medical Society, died at the Burwell Infirmary, Selma, Ala., from pneumonia, after a short illness, on March 7, aged 34 years.

Dr. N. B. Coffman of Healdsburg, Cal., a graduate of the Miami Medical College, Cincinnati, Ohio, in 1883, died at San Francisco, from apoplexy, suddenly on March 5.

Dr. Charles A. Smith of East St. Louis, Ill., a graduate of the Barnes Medical College, St. Louis, in 1897, died at Chicago, after a long illness, on March 8, aged 45 years.

## Obituary.

### GEORGE McNAUGHTON, M.D.,

NEW YORK.

Dr. George McNaughton, clinical professor of gynecology in the Long Island College Hospital, Brooklyn, died at his home from heart disease, after a long illness, on March 17, aged 57 years. Dr. McNaughton was graduated from the Bellevue Hospital Medical College, New York, in 1878, and had practised in Brooklyn since that time. He was a member of the American Medical Association, the New York State and Kings County Medical Societies, the Academy of Medicine, the New York Obstetrical Society, the Brooklyn Gynecological Society, and the Brooklyn Pathological Society, visiting gynecologist to the Long Island College Hospital, the Kings County Hospital, and the Brooklyn Eastern District Dispensary, consulting gynecologist to the Long Island State Hospital and the Brooklyn Central Dispensary, and chief of the gynecological division of the Jewish Hospital, Brooklyn.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

MILROY LECTURES AT ROYAL COLLEGE OF PHYSICIANS —SPREAD OF BACTERIAL INFECTION: ABSORPTION —REGISTRATION OF NURSES' BILL—LONDON HOSPITAL ATTACKED—ANNUAL MEETING MIDDLESEX HOSPITAL—LISTER M'MORIAL—RESEARCH COMMITTEE AND ADVISORY COMMITTEE—OBITUARY.

London, March 6, 1914.

At the Royal College of Physicians last evening Dr. Shufflebotham delivered the concluding lecture of the Milroy course. He has dealt freely with the hygiene of coal mining and the diseases of that industry and pointed out that although much has been done to improve the health of miners the death toll is still too high and the non-fatal injuries should also be reduced. He advocates thorough and systematic inspection of mines and suggests that the time has come for specialization in mining and more extended training of the engineers in the sciences involved. So, too, he thought something has been lacking in the medical schools which have not made specialties of industrial diseases. Considering the tens of thousands of pounds spent on tropical diseases and with very good results, the lecturer thought it strange that so little had been done for these industrial diseases prevailing in our midst. Thousands of practitioners working in mining districts have never received a lesson on diseases they were continually called upon to diagnose and treat. Their experience had been acquired at the expense of their patients, and he held that it would be well if instruction on this branch were given in the universities and schools. Then young men who intended to practise in industrial districts could become conversant with the conditions which would specially concern them.

There is much to be said for the lecturer's suggestion—particularly perhaps in relation to injuries, the surgical division—but it may be said, on the other hand, that college courses are not everything and the curriculum is very full. And respecting those who know they will practise in these districts, they have opportunities of making especial preparation for doing so.

A plan I have known adopted and which deserves commendation is to serve for a time under an experienced practitioner either as an assistant or junior partner in a locality affording the desired opportunity of studying the diseases and injuries in question.

An interesting account of work on the channels of spread in bacterial infection carried on by Drs. Thiele and Embleton has been communicated to the Pathological Section of the Royal Society of Medicine. They show that the mucous membrane of the urethra is very permeable to the organisms which reach the heart's blood and become generally disseminated within two hours. They spread by way of periureteral lymphatics to the capsular lymphatics of the kidney to the thoracic duct, and it was suggested that this rapid passage might account for catheter fever. The vaginal membrane did not seem permeable, nor did the conjunctiva. By feeding animals with bacteria infection occurred through the buccal membrane by way of lymphatics to the salivary glands and the lymphatics connected with them and the cervical glands. The lungs did not keep back bac-

teria reaching them by way of the thoracic duct from which they were generally disseminated. Inoculated into serous cavities the organisms were entirely absorbed along the lymphatics. The absorption was extremely rapid as they were demonstrated in the blood within two minutes after intraperitoneal inoculation. Diffusible substances were absorbed both by lymphatics and blood channels. From their experiments the authors deduce the following conclusions: 1. Bacterial spread is primarily by way of the lymphatics, the bacteria rapidly passing to the thoracic duct and blood stream and undergoing general dissemination. 2. Bacteria do not have specific sites of predilection peculiar to themselves; with every infection after gaining access to the thoracic duct general dissemination occurs, and if looked for at the proper time can be found in every tissue, the sites in which they can ultimately be found depending on the rate at which they are destroyed in the organ. 3. The lungs do not act as filters. 4. Whenever bacteria occur in the blood they are excreted in the urine, and there is no need to suppose increased permeability of the kidney for this purpose. 5. Bacteria cannot pass from the lymphatics into the urine: the capsular lymphatics of the kidney may be full of bacteria, but they only get into the urine after gaining access to the blood. 6. Even when general bacterial dissemination occurs the serous cavities remain free from infection for a very long time.

A bill for the registration of nurses was introduced into the House of Commons on Tuesday by Dr. Chapple, who produced a good deal of indignation by making an attack on the London Hospital, which is not in favor of the project and which he charged with exploiting nurses for its own financial interests. Protests were raised at his statements and an appeal made to the Speaker, who rebuked the honorable member, informing him that the proper course to take in introducing a bill is to state its objects and explain its causes, not to make attacks on institutions with no representation present. Dr. Chapple asserted his bill had the support of the General Medical Council of the British Medical Association and of all institutions connected with nursing. But he can hardly deny that the largest hospital is connected with nursing, and many will be inclined to consider its experience of more value than his opinion.

Possibly registration may be desirable, though many objections may be raised. Good nurses have no need to protect their interests and their merits have been fully recognized by the public and the profession. Inferior ones are to be found and they are generally forward to assert themselves and even to usurp the function of the doctor. Registration would hardly check this defect and certainly would not eliminate such persons.

As to the London Hospital, so improperly attacked, important developments were reported at a meeting of governors on Wednesday. The quinquennial appeal realized over £100,000, or more than £30,000 above the amount in 1908. During the past year 17,096 in-patients were treated, the daily average being 795, a decrease in the meantime of each patient's residence (17.78 days, compared with 18.59 days in 1912), was considered as probably due to the development of modern surgery, operations being attended with less shock and therefore patients being able to leave the hospital sooner. During the year anesthetics were given in 22,080 cases; out of this number only seven fatalities occurred, and they were mostly of patients already *in extremis*. Out-patients showed considerable decrease, perhaps due to the insurance act. A development about to be taken in hand is the building of special wards for the treatment of syphilis, toward which the Grocers' Company has offered £10,000. The wards will consist of separate rooms, with laboratories, and the committee states that in undertaking this advance they regard it as a "momentous step" and one which "it is hoped will be followed by other hospitals throughout the country" with a view to the "ultimate eradication of syphilis." Further plans have been drawn up for building aural wards, and a site has been selected for a hostel for the resident medical staff, which will set free rooms for extending other departments.

The chairman of the hospital, Viscount Knutsford, so long known as Hon. Sydney Holland, has undergone an operation and it was announced at the meeting that he was doing as well as possible.

At the annual meeting of governors of the Middlesex Hospital on Friday it was stated that the donor of the £15,000 for building an institute of pathology was Sir John Bland-Sutton, who at that time desired to remain anonymous for reasons no longer existing. Prince Alexander of Teck said mere words could not express their obligations for this munificence and he looked for some one else who could afford it to help them in the same spirit to maintain the new instrument put in their hands. Sir R. Douglas Powell testified to the efficiency of the in-patient department and Lord Cheylesmore to the satisfactory financial status of the hospital on the whole.

The committee of the Lister Memorial Fund has commissioned Sir Thos. Brock, R. A., to execute the medallion portrait to be placed in Westminster Abbey, forming part of the International Memorial.

A medical research committee to administer the funds available for research under the insurance act has been constituted by regulations published yesterday. An advisory council of research has also been appointed. The research committee, it is laid down, shall from time to time prepare schemes for research, including, if the committee think fit, schemes for inquiries and the collection and publication of information and statistics, and shall submit such schemes to the chairman of the Nation Health Insurance Joint Committee for approval. Before giving his approval the chairman shall consult the advisory council.

Dr. George Moore, Deputy Inspector-General of Hospitals and Fleets, died at the age of 86. He entered the naval medical service in 1848, became staff surgeon in 1857, fleet surgeon in 1870 and department inspector-general in 1882, retiring the same year. He served in the Russian War, 1854-5. In 1856 he had medical charge of expedition against Indian tribes in Vancouver Island and was specially commended for his services. He has also been surgeon at the Royal Dockyards at Chatham and Portsmouth and P. M. O. at Pembroke Dock.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

### WORK OF THE BUREAU OF HEALTH—STERILIZATION OF WATER.

MANILA, P. I., January 31, 1914.

THE semi-annual report of the Bureau of Health states "that there are now over 60,000 fewer deaths in the Philippines per annum than there were in

1905. This reduction has occurred almost entirely among the preventable diseases and may therefore be regarded as an index of the effect of health work in the Philippine Islands. There is room, however, for further improvement. Tuberculosis, malaria, beriberi, and intestinal diseases, all of which are preventable, are still responsible for more than a hundred thousand deaths annually. The results which have already been achieved should act as a stimulant to the effort to make a large reduction in this number during the next few years. The knowledge with which to accomplish this is available and it is only necessary to apply it faithfully. A substantial start toward this goal has been made.

"It is estimated that malaria is responsible for at least 25,000 deaths annually. If each of these victims could have been treated with an adequate amount of quinine, practically all of these lives could have been saved. By the cooperation of various branches of the Government, arrangements have now been completed for the sale of quinine at a nominal rate by over 700 municipal and township treasurers throughout the Islands. In addition, several million doses of quinine are being distributed gratuitously among the poor.

"Knowledge with regard to the manner in which beriberi may be prevented is being rapidly disseminated among the masses and a reduction in the number of deaths from this disease may now be expected.

"A circular of information as to the proper disposal of human excreta has been completed and a general adoption of the system therein advocated will result in the saving of many thousands of lives.

"The Manila and provincial hospital system has now been extended to the full limit of the amount of Insular aid which may reasonably be expected for its maintenance, and further progress along these lines should come from funds made available by provincial or municipal governments or private individuals.

"Briefly, there is enough work outlined, the accomplishment of which will pay heavy dividends in the form of lives saved, to use up all of the appropriations which are in sight. Until more money is available, additional projects which require the expenditure of substantial amounts can at present not be undertaken.

"It is doubtful whether any country has ever reaped such large returns in improved health and reduced mortality as have been realized in the Philippine Islands. The tremendous reduction in the death rate referred to above has been brought about by an expenditure of about 20 centavos per capita per annum, and when it is remembered that the results were obtained under a strictly civil régime where each obstacle had to be conquered by persuasion or laboriously fought through the courts, it is indeed remarkable that the results should compare so favorably with those achieved under military régime."

In order that small restaurants, eating houses, refreshment counters, etc., may furnish a safe drinking water to the public at a reasonable cost, the Bureau of Health has recommended that all of them install plain teakettles for rendering drinking water sterile. From time to time prosecutions are made, whenever it can be shown that the water contained amebæ or pathogenic bacteria, this being considered evidence that the water has not been properly sterilized and protected. Some complaint has been made by the persons affected, who stated that the water had been properly boiled and that it must have been contaminated later. In order to have definite information available, an investigation was made at the Bureau of Science. It was found that water that had been thoroughly boiled and left exposed to the room atmosphere and then examined bacteriologically gave the following results:

| | 16 Hrs. | 22½ Hrs. | 41 Hrs. | 3 Days | 5 Days | 7 Days | 9 Days | 12 Days | 14 Days |
|---|---|---|---|---|---|---|---|---|---|
| No of colonies per c.c. | 8 | 8 | 74,183 | 31,550 | 279,000 | 172,000 | 134,850 | ..... | 260,000 |
| Presumptive test | — | — | — | + | — | — | — | — | — |
| Attempt to isolate *B.coli*. | — | — | — | — | — | — | — | — | — |
| Amebæ | — | — | — | — | — | — | + | + | + |
| Ciliates | — | — | — | — | — | — | — | — | — |
| Flagellates | — | — | — | — | — | — | — | + | — |

When a similar receptacle was loosely covered by a box, the results were as follows:

| | 16 Hrs. | 22½ Hrs. | 41 Hrs. | 3 Days | 5 Days | 7 Days | 9 Days | 12 Days | 14 Days |
|---|---|---|---|---|---|---|---|---|---|
| No. of colonies per c.c. | 2 | 70 | 149,800 | 976,500 | 290,625 | 93,000 | 18,317 | 508 | 18 |
| Presumptive test | — | — | — | — | — | — | — | — | — |
| Attempt to isolate *B. coli* | — | — | — | — | — | — | — | — | — |
| Amebæ | — | — | — | — | — | — | — | — | — |
| Ciliates | — | — | — | — | — | — | — | — | — |
| Flagellates | — | — | — | — | — | — | — | — | — |

Water similarly boiled and exposed to the dust of an animal house gave the following results:

| | 18 Hours | 3 Days | 5 Days | 10 Days | 12 Days |
|---|---|---|---|---|---|
| No. of colonies per c.c. | 376 | 558,000 | 325,200 | 74,400 | 111,600 |
| Presumptive test | — | + | + | + | + |
| Attempt to isolate *B. coli* | — | — | — | — | — |
| Amebæ | — | — | — | — | — |
| Ciliates | — | — | — | — | — |
| Flagellates | — | + | + | + | + |

When loosely covered with a box the presumptive test was negative and no organisms could be found at the end of 12 days. The numbers of colonies were as follows: 18 hours, 8; 3 days, 3,816; 5 days, 26,737; 10 days, 20,925; 12 days, 6,754. From the foregoing experiments it is shown that there is a progressive increase in the number of bacilli and then a diminution. The contamination is very much less in a covered can. It will therefore be apparent that laboratory examination for the presence of amebæ and pathogenic bacteria in water that is presumed to have been boiled within 48 hours from the time that it is used may serve as satisfactory evidence to present before a court.

## Progress of Medical Science.

**Boston Medical and Surgical Journal.**

*March* 12, 1914.

1. Vaccination Efficiently Performed. E. F. Cody.
2. Correlation of Cerebrospinal Examinations with Psychiatric Diagnoses. A Study of 140 Cases. Mary E. Morse.
3. Two Cases of Lung Abscess Cured by Operation. W. Whittemore.
4. Prostatectomy Without Irrigation. A. E. Rockey.
5. A New Operation for Hip Contractures in Poliomyelitis. R. Soutter.
6. The Trephine Operation in Glaucoma. M. Standish.
7. The Simplification of the Technique of Reposition of the Retroverted Uterus. J. T. Williams.

**1. Vaccination Efficiently Performed.**—E. F. Cody points out that variola no longer prevails in countries where vaccination is regularly and efficiently performed. Where this important sanitary measure is irregularly practised, as in the United States, the disease recurs at

intervals, less severe than in former times, but nevertheless with considerable mortality and at a large cost to the community. The progress of preventing smallpox in a country like ours, where vaccination is optional after the age of entrance to public schools, is rendered difficult by persons who would have others believe that the procedure is useless, harmful, or fatal. The author concludes that vaccination is a surgical procedure and demands surgical asepsis. The patient must be under the supervision of the physician until scar formation, when a certificate may be given. He should be told that his immunity is for a limited time; if liable to exposure he should be revaccinated. As those countries are most free from smallpox where vaccination is regularly imposed, a revaccination of all persons should be required at stated intervals. Vaccination should be done with a minimum of trauma. The experience of most observers warrants two or more incisions. Vaccination efficiently performed protects against smallpox. Vaccination efficiently performed silences opposition.

2. **Cerebrospinal Fluid in Psychiatry.**—Mary E. Morse concludes that the scarcity of actual correlations between findings in the cerebrospinal fluid and psychiatric diagnoses in any considerable series of cases makes of value a review of the results in a large general hospital. The examination of the serum and cerebrospinal fluid leads to a reduction in the number of cases diagnosed as general paralysis. The cases which have been found most difficult to differentiate from paresis without examination of the serum and cerebrospinal fluid are cerebral syphilis and arteriosclerosis and Korsakow's psychosis. In regard to cerebral syphilis, however, it must be said that although the findings in the serum and cerebrospinal fluids are supposed to be sufficiently characteristic to permit a differential diagnosis from paresis, in the individual case they frequently leave one in doubt. In a large insane hospital the routine examination of the serum and cerebrospinal fluid finds, perhaps, its most immediate value in the rapid confirmation or elimination of the suspicion of paresis in new patients and in revision of the diagnoses of certain patients admitted in pre-Wassermann days.

7. Quinine and Urea Hydrochloride in Nose and Throat Surgery. A. J. Herzig.
8. Medical Contract Practice. S. A. Tannenbaum.

1. **Diverticulitis of the Colon.**—J. J. Erdman points out that left-sided appendicitis is the rare rather than the occasional cause of involvement of the left side. If there is left-sided pain with a mass or not, with tenderness, rigidity, etc., one can be relatively certain of diverticulitis. In cases of previously known or surmised malignancy of the sigmoid, such acute evidences point to an ulcerating perforation above the malignancy. Prolonged chronic diverticulitis frequently becomes cancerous. Many heretofore reported instances of cancer of the intestine have been cases of chronic diverticulitis only.

2. **Tubercle Bacilli Submerged in Water.**—R. C. Rosenberger concludes from his studies that the most important point in the prevention of tuberculosis is insistence upon the complete disinfection of the feces of a tuberculous subject, as well as of the sputum and urine, with a powerful germicidal agent. There should be a more rigid inspection and examination of dairy cattle for the detection of tuberculosis, and the presence of tubercle bacilli in the milk and feces of apparently healthy animals. The water supply of a village, town, or city should be safeguarded principally by the prohibition of dumping sludge in streams; the proper filtration of water; where there are no facilities for filtration, the boiling of water for drinking purposes; the rigid inspection of drainage of sanatoria for the care of tuberculous subjects; and the prohibition of dumping slaughterhouse refuse into streams; that one should insist upon the pasteurization of milk for infant feeding, or the general heating of this food for twenty minutes at 60° C. for the destruction of tubercle bacilli and other toxicogenic bacteria and products. Sludge retained in septic tanks should not be used for fertilizer unless sterilized. Instead of allowing sludge to accumulate for several months before cleaning the tanks, these receptacles should be cleaned at regular stated intervals, say once a month, and the sediment then sterilized or collected, dried, and incinerated. The cremation of those dead from tuberculosis, should be demanded, because of the great vitality and resistance of the tubercle bacilli.

5. **Tobacco and Mental Efficiency.**—A. D. Bush performed a series of 120 tests on each of fifteen men, in several different psychic fields, which tests apparently show that tobacco smoking produces a 10.5 per cent. decrease in mental efficiency. The greatest actual loss was in the field of imagery, twenty-two per cent. The three greatest losses were in the fields of imagery, perception, and association. The greatest loss occurred with cigarettes. Nicotine was not found in the smoke of any tobacco, except that of cigarettes, and then only in traces. Nicotine was found in the distillates of all tobacco tested. Pyridine was found in the smoke of all tobaccos tested, and seems to be the principal toxic factor in the smoke.

6. **Adenomyoma of the Rectovaginal Septum.**—T. S. Cullen reports two cases of adenomyoma of the rectovaginal septum. This condition is of considerable surgical interest; it is not histologically malignant and does not give rise to metastases. In the early stages, as shown in one of the cases, the growth can be removed without injury to the rectum but when the rectal involvement is extensive, resection will as a rule be needed. The immediate differential diagnosis between the adenomyomas and cancer of the bowel is of the utmost importance. If the uterus contains myomas the probability of an adenomyoma is strengthened. If the growth appears to be muscular, it is still more probably an adenomyoma and if the growth is cystic, it is al-

most certainly a myoma. There is no rectal hemorrhage and the only symptom is pain on defecation. The removal must be complete, as portions left will continue to grow and cause complications. The operation for cancer must necessarily be more extensive. The cases reported emphasize the necessity of careful microscopic control of all rectal growths as they might easily be mistaken for carcinomas. The author insists upon the careful isolation of the ureters and the removal of the uterus altogether as in the Wertheim operation. It would be wise to place a delicate protective drain but to keep it away from the suture line in the bowel. If a large part of the lumen of the bowel is involved, its resection will be necessary. The author believes that with the careful examination of all rectal or perirectal growths, many cases similar to those reported will be found.

7. **Dangers Attending Pyelography.**—J. M. Mason states that pyelography by use of collargol injections and the roentgenogram has come into favor to a considerable extent in this country chiefly through the writings of Braasch and the reports of the Mayo clinic in none of which has the author found reference to any injurious effects following the use of the method. He reports two cases of his in one of which the patient suffered intensely from pain, nausea, and vomiting and had a slight rise of temperature for four days. When the kidney was removed five days later its surface showed numerous nodules with black discoloration beneath the capsule. On section each nodule proved to be the outer surface of an infarcted area, deeply stained with collargol and the different infarcted areas showed different degrees of inflammation. No collargol remained in the kidney pelvis. A few days later a patient with renal tumor—a hypernephroma—was injected with collargol, care being taken to use a smaller quantity and to stop at the first appearance of pain and leave the catheter in the ureter until it was thought the collargol had all drained away. No special constitutional effects were noted but on removing the tumor ten days later, there were found a few of the discolored nodules on its surface and the same black infarcts on section. The kidney contained a quantity of precipated collargol. The microscopic examination showed widespread collargol deposit in the kidney substance, collargol stained deposits and granular casts throughout the tubules and many of the malpighian corpuscles showed collargol masses within the capsule of Bowman. No definite evidence of inflammatory reaction was seen in the collargol-containing tubules outside the necrotic areas but in some areas tube-casts both stained and unstained were more numerous than one would expect as a result of the primary condition. A definite sequence of events follows injection of the renal pelvis, if the intrapelvic pressure is raised beyond a certain unknown point. The pelvis is overfilled and the injected material, together with any infectious matter in the pelvis, passes up into the convolnted tubules and glomerated capsules, and may be followed by rupture of the tubules and production of infarcts or abscesses. Whether or not the collargol has any irritating or cauterizing action in the process is in dispute. Damage may result from conditions not entirely under one's control in the injection of the kidney and that such injection is contraindicated in the presence of infection and where the integrity of the kidney has been impaired by injury or disease.

1. Glycosuria and the Albuminuria of Adolescents. Sir James F. Goodhart.
2. Infantilism. Hastings Gilford.
3. The Morbid Anatomy of Tuberculosis in Man. T. Shennan.
4. The Significance of Diabetic Family History in Life Assurance. O. May.
5. The Pathological Changes of the Thyroid in Disease. R. Farrant.
6. Case of Acute Suppurative Appendicitis Complicated by Gangrene of the Ileum. B. Hughes.

1. **Glycosuria and the Albuminuria of Adolescents.**—Sir James F. Goodhart notes that the presence of sugar in the urine of young people means diabetes, and diabetes usually of a severe grade; but that in those of advancing years it by no means necessarily means diabetes, or, at any rate, that the disease is far less likely to be of grave import. True diabetes, commencing as such, with all the classical symptoms, may, under treatment, continue for many years, and even into the declining decades of existence. The author is even strongly inclined to believe that all glycosurias, no matter at what time of life they occur, have something in common—an epileptiform or migrainous paroxysmalism. For many years these people are not in danger so much from their glycosuria as such—with which alone indeed they may live many years, or to old age—as they are from a slowly maturing chronic Bright's disease or what is now called arteriosclerosis. These are the cases that exhibit retinal changes with their glycosuria. Adolescent albuminuria presents another problem in biochemistry. The author refers to it as the paroxysmal albuminuria of the young. It is not ill-coupled with glycosuria, for each is both paroxysmal and functional. It is an albuminuria of more or less, sometimes of large, quantity, found in boys and youths from any age up to 19 or 20, and may be in young men up to 24 or 25 occasionally. It is not known to be nearly as frequent in girls, but this may be because the urine in them is not so often examined, and the periodical function interferes with, perhaps even prevents the occurrence of albuminuria. The condition occurs preponderatingly in overgrown and weedy youths, in those, at any rate, who have been growing rapidly, and also in the food bolter, but there are frequent exceptions. It may be present in many individuals in whom it is hard to say there is any ill health. It sometimes disappears almost as soon as it is noticed, but more characteristically it comes and goes over a long period, maybe of months or years. But the cardinal characteristic of the affection is that at one time of day—usually the first thing in the morning—there is only a trace of albumin or none at all, at another there may be a large quantity. One other feature is that invariably in these cases a precipitate of globulin is obtained from the urine by adding a drop or two of strong acetic acid.

2. **Infantilism.**—Hastings Gilford presents the second of his lectures on this subject. He notes that ateleiosis is prone to be associated with other anomalies of development, such as anomalies in the organs of sex, thyroid insufficiency, and abnormalities of the pituitary body. The most rational explanation of these errors by defect is that they are reversionary. The dwarf races of Asia and Africa represent peoples in a state of racial stagnation or infantilism.

3. **Morbid Anatomy of Tuberculosis.**—T. Shennan states that in Scotland the maximum death rate from tuberculosis occurs during the 25-35 age-period; in England during the 35-45 age-period. In Scotland the maximum percentage death-rate from tuberculosis calculated on the number of deaths from all causes, at each age-period, occurs in the female during the 15-20 age-period, and in the male during the 20-25 age-period. The percentage of deaths from tuberculosis in females during the 15-20 age-period is 52.69. The death-rates from tuberculosis in different towns and

cities in Scotland bear no clear relationship to the number of inhabitants or to the density of population. Other factors must be involved. Hypersensitiveness due to a primary infection is probably of great importance in relation to reinfections. Reinfections arise not necessarily from a previous focus in the body, but must frequently be new infections from without. The majority of cases of tuberculosis of the lungs and their regional glands are the result of aerogenic infection. Retrograde infections do occur. There is no evidence in favor of a spread by direct continuity from the deep cervical glands to the lungs. The right lung and its regional glands are more often the seat of tuberculosis than the left. In children manifest tuberculosis of the lung is very frequently a sequel of tuberculosis of the bronchial glands. Little satisfactory is known of the factors which determine the localization of the disease in the lung. Chronic fibro-caseous tuberculous foci in the lungs and caseation of the related bronchial glands may be caused by separate infections. In Scotland bovine infections in childhood are commoner than in most other parts of the world. The relative frequency with which bovine or human infections occur in any given organ or tissue, and the differing incidence of these infections in different localities, depend on the relative general frequency of infections with these two types of the tubercle bacillus. This differs in different localities.

9. Further Note Upon a Case of Hysterical Monoplegia Following Electric Shock. Purves Stewart.

**1. Anthropology of Shakespeare and of Burns.**—A. Keith has made a careful study of certain portraits of the above poets, and has compared them with prehistoric skulls found in England. He finds that the two national poets are representative of two of the most divergent of European stocks. If the term "Celt" is used in the same sense as it is employed on the continent of Europe then Shakespeare must be called a Celt—a descendant of the round-headed people who invaded England in the Bronze Age. Burns is from the western fringe, usually called Celtic, but which is pre-Celtic. He comes of the long-headed stock which inhabited England before the Bronze Age—probably before the Neolithic Age dawned. Possibly the extraordinary difference in the working of their brains is to be explained by the diversity of their racial origin.

**3. Pathological Changes of the Thyroid in Disease.**—R. Farrant has shown that the pathological changes of exophthalmic goiter could only to a certain extent be reproduced by thyroid feeding in cats, rabbits, guinea-pigs, and dormice, and, as was to be expected, hyperplasia of the thyroid was one of the changes that could not be reproduced. He has also demonstrated that a hyperplasia of the thyroid microscopically similar to that of exophthalmic goiter was to be found in diseases such as infantile diarrhea, measles, diphtheria, and whooping-cough, and that it could be artificially induced in guinea-pigs by the injection of diphtheria toxin. The following diseases induce a colloid chronic hyperplasia: chronic coliform infection; chronic tuberculosis; Malta fever, meningococcus infection, tertiary syphilis, actinomycosis, poliomyelitis, rheumatism, scarlet fever, chronic nephritis, and pernicious anemia. The diseases which cause a complete or acute hyperplasia are infections with *Aerogenes capsulatus* (?), anthrax, colon bacillus in guinea-pigs, diphtheria in man, diphtheria toxin in horses and guinea-pigs, dysentery, Gaertner bacillus, glanders, tetanus, acute tuberculosis, *Micrococcus catarrhalis*, secondary syphilis, malaria, measles, bronchopneumonia, and smallpox (?); and whooping-cough and chronic nephritis, cirrhosis of the liver, and the artificial toxemias caused by abrin, ricin, and the diphtheria toxin.

**4. Dissemination in Carcinoma of the Rectum.**—J. W. Heslop reports a case of carcinoma of the rectum in a man aged 26 years. The history of this case brings out a number of important points. It shows that the extramural spread of carcinoma of the rectum may be very far advanced, even into the abdomen, whilst the primary focus in the wall is small and difficult of recognition. It demonstrates the value of the laparotomy which necessarily precedes abdominoperineal resection of the rectum in determining the presence or absence of secondary intraperitoneal deposits, which may contraindicate an extensive and useless removal. Limited removal as obtained by perineal excision, or even Kraske's operation, in this case would have left most of the disease uneradicated, despite the low position of the malignant ulcer on the rectal wall. Occurring in a young man, it shows that the age incidence of carcinoma is variable, and that its virulence is probably greater in the young than in the old.

**6. Alcohol, Housing Conditions, and Tuberculosis.**—H. Vallow notes that alcoholism is more prevalent amongst the male consumptive patients than amongst the normal male population, and also appears to be in excess amongst the females. This does not necessarily mean that alcohol, of itself, has a great deal to do with the onset or progression of consumption, but it does mean that alcoholism, with its associates—late hours, irregular feeding, the poverty which it may entail, the crowding together in ill-ventilated public-houses where the best hygienic conditions do not obtain—has a considerable bearing on the consumptive question. If alcohol habits can be taken as an indication of the habits of consumptive patients of the poorer class, the author's figures point to the conclusion which he has held for some time—that if consumption is to be eradicated the habits of a large number of the patients will have to be greatly improved. As regards housing conditions in relation to tuberculosis, the author points out that there is more phthisis in back-to-back houses with no through ventilation than in good, through, well ventilated houses. As contact with tuberculosis cases is likely to play an important part in the spread of the disease, it is necessary that the people concerned should be told of the great danger they are running, as there is ample proof that such a danger does exist.

**7. Visceral Lesions of Purpura.**—Sir William Osler states that the visceral lesions in this disease are of two types. First, mechanical, due to the presence of exudate in the walls of the stomach or intestine, effusion of blood on a mucous surface, or into the substance of an organ; secondly, inflammatory, as nephritis, less often endocarditis, pleurisy, pericarditis, pneumonia, or peritonitis. The cases have a dual etiology, infectious and metabolic. Purpura, with or without erythema and exudative lesions, may follow gonorrhea, otitis media, parturition, phimosis, and local lesions of the skin. The rheumatic poison is believed to be responsible for a large group; and in the case of a child with severe purpura in the third and again in the fifth year, chorea in the sixth without

endocarditis, severe urticaria in the same year with ill health, chills, fever, and well-marked endocarditis, such a view is probably correct. The arthritis, too, is held to indicate the same cause, but it may have a very different explanation. The bacteriological examination of these cases has not been very satisfactory—no unanimity has been reached as to the organisms. On the other hand, there is a large group in which the lesions are an expression of perverted metabolism. Chronic angioneurotic edema, urticaria, and some forms of purpura are possibly anaphylactic phenomena in persons sensitized for certain protein substances. It is interesting to note that experimental sensitization may be transmitted. Hay fever, the idiosyncrasy to iodine, quinine, to strawberries and shellfish, are all manifestations of this supersensitiveness. The phenomena of serum sickness reproduce in a graphic way the features of the skin diseases which the French group under erythema. The local edemas, the urticaria, the purpura, the arthritis, the vomiting, and the persistence for years of the sensitiveness, are paralleled by the lifelong liability to recurrence in some cases of angioneurotic edema and of purpura. With reference to the cerebral manifestations the author notes that there are two groups of cases—the one with transient attacks of paresis, such as occur in Raynaud's disease and in arteriosclerosis; the other in which the paralysis is due to coarse hemorrhage. As regards ocular lesions the author points out that in anemia and leucemia, in cachectic states, and in arteriosclerosis retinal hemorrhage is common, conjunctival less frequent. In the hemorrhagic types of the specific fevers extensive bleeding may take place, and in black smallpox. The author has seen the corneæ sunk in a wall of subconjunctival hemorrhage. In purpura hæmorrhagica bleeding may take place into the eyeball. To the gastrointestinal symptoms the most distressing though not the most dangerous of the visceral complications, the name of Henoch is given when associated with purpura, though they occur with any member of the erythema group of skin lesions. The manifestations may be for years abdominal without skin eruptions. Colic is the common symptom, and occurred in 25 out of 29 cases analyzed in 1904. The attacks may be transient, lasting only a few minutes, but recurring several times during the course of the day. They may be of great severity, causing the patient to writhe in the bed. They occur most frequently at night. The attacks are independent of diet, and occur with the skin rash or in the intervals of the outbreaks until the rash fades. In protracted cases the colic may not appear for a couple of months, and then be very severe. The position of the pain is usually central, and may radiate to all parts; very often the child cannot fix upon the spot accurately. The author never met with an instance in which the pain was limited to the right iliac fossa. The abdomen is usually flat, not painful on pressure, without increase in the muscle tension, though it may often be difficult to palpate the child satisfactorily. There may be marked tenderness along the transverse colon. Vomiting, with or without pain, is perhaps quite as frequent as colic, with which it is very often associated. The renal complications are the most serious of the whole group. They fall into three groups: (1) those which run an acute course with dropsy and death in uremia within three months. In a second group the albumin disappears and the patients get perfectly well. In a fortunately small number of cases the nephritis becomes chronic.

---

Berliner klinische Wochenschrift.

*March* 2, 1914.

**Experimental Vaccine.**—Gins refers to Fornet's recent work in ether sterilization of ordinary vaccine and in cultivation of the exciting cause of variola. This is not the ordinary sort of bacterial cultivation after complete isolation of the microorganism, but an indirect cultivation of germs embedded in the so-called vaccine corpuscles. Aside from Fornet himself, investigators do not find evidence that any increase in germ life occurs through the use of the raw material for inoculation. The vaccine corpuscles, in other words, do not come up to the requirements of a specific virus. It has also been shown that heat above 37° C. may prejudice the activity of the virus, just as when ether is used for quick sterilization of vaccine lymph. The author also takes up Rabinowitsch's claim and contends, along with Fornet, that the streptodiplococcus of the Russian cannot be the cause of variola. As far as priority claims exist between Fornet and Rabinowitsch, that of Belin (1909) should also enter into competition. The author's technique is borrowed in part from that of workers in other kinds of virus. In diluted vaccine lymph shaking up with kaolin causes the virus to adhere to the kaolin sediment, the fluid remaining for the most part free. In other words, a most vigorous absorption between the kaolin and virus has resulted. That no mere mechanical adhesion is involved is shown by the fact that washings from the kaolin show no virus present. The author sees in this phenomenon a promise of future success.

**A New Manifestation of Hypothyreosis.**—Heinrich Stern of New York claims to have discovered in this condition a peculiar doughy submucous infiltration of the lower urinary tract hitherto undescribed. The subject is not a new one outright, but in the older literature a different interpretation has been given. Of four of the author's cases but one was in a man, and all the patients showed the ordinary phenomena of myxedema, which robs them of a certain amount of interest. The author sums up his cases and their type as follows: in a case of hypothyreosis with frequent or painful desire to urinate, one should perform cystoscopy. In the case of children, as expressed by enuresis, the cystoscope need not be used, but in either case thyroid preparations should be given.

**Forced Feeding in Childhood.**—Engel refers to the older ideas on this subject, which emphasize the difficulty of making children eat, or at least to eat by rule. To stuff children may mean to take away what appetite they may have. In the majority of these cases if cream can be taken daily the problem is solved. The author prefers to give the cream all at once, so as to leave the stomach to itself for the balance of the day. The cream is best given at bedtime, beginning with a small dose and increasing it indefinitely. Take the example of a ten year old boy who weighs 30 kilo (normal) and whose rest requirement of caloric is 1250. This must be supplied from the ordinary diet, leaving the cream as a surplus. It may be made to supply from 30 per cent. to 50 per cent. more of the diet, the patient still being at rest. To promote or facilitate rest the author would give some form of bromide. Fowler's solution should also be given. When the weight has been brought up to normal, the cream should still be given, even during school life.

Münchener medizinische Wochenschrift.

*February* 24, 1914.

**Case of Polyneuritis and Korsakow's Psychosis After Neosalvarsan; Fatal Ending.**—Pürckhauer and Mauss seem to have shown that toxic substances other than alcohol are able to produce the Korsakow syndrome. A woman aged 57 with marked history of syphilis was

just developing tabes. When first seen was well nourished and sound mentally. No signs of approaching paresis. A few symptoms of pretabes; Wassermann reaction positive. Two injections of neosalvarsan, one week apart, the first without reaction. After the second, fatigue set in with somnolence and anorexia. No further symptoms. Two days later failing memory apparent. As the other symptoms receded the memory failure increased, especially for recent events. It also showed individual peculiarities in connection with present events. No speech disorders, and no other psychic symptoms save those due to the memory failure. After a physical examination the diagnosis was tabes, polyneuritis, and Korsakoff's psychosis. The latter rapidly developed disorientation and complete confusion. Intellect preserved. Patient knew her condition, answering rationally. She perished slowly of asthenia and autopsy was refused. Aside from tabetic symptoms, patient presented a classical Korsakoff or amnestic psychosis. The extreme muscular fatigue was the result of polyneuritis. It may of course be asserted that the cerebropathy following directly upon incipient tabes argues for a form of paresis; also that tabes is sometimes closely simulated by polyneuritis. The author defends his diagnosis without difficulty, but the question remains "how can salvarsan cause Korsakoff's syndrome?" The arsenic could explain the polyneuritis; to account for the psychosis is more difficult. But we know that certain toxic substances simultaneously attack the nerves and brain (alcohol, lead); and it is probable that arsenic caused the cerebropathy as well as the polyneuritis.

**Grape Juice in Europe.**—Bender writes at length of this drink as a possible substitute for alcoholic beverages. Any reference to the U. S. A. or to Secretary Bryan in this connection is not to be found. One method of preparation consists of heating the must to about 95° C. until all germs are destroyed, and most of the albumin thrown out (this furnishes the pabulum for the germs). The supernatant fluid is now bottled airtight and pasteurized. The sugar remains, but the bouquet and nitrogenous matter are lost. Heating gives a tamarind taste, which is unpleasant to many. It is also impossible to place the article on the market at a low price. To improve conditions Monti in Italy freezes the must in part, the remaining solution being well condensed. To supply the wine flavor an aqueous extract of the remains of the grapes is added, so that the tartaric and tannic acids are preserved. Specimens by this method are without the disagreeable taste already mentioned. The Italian juice like the German must be bottled airtight and then sterilized. Dilution with three or four parts of water is advisable for economy's sake. When grape juice is evaporated, it is known as grape honey and in this form may be readily marketed. Diluted with water it becomes grape juice. As honey it possesses the power of taking up albumins, sugars, etc., and "tinctures" of drugs may be prepared from it instead of alcohol. In the former capacity it possesses great feeding possibilities, as solutions of eggs, milk, casein, etc., are clear. The rationale of this "predigestion" is not explained.

## Deutsche medizinische Wochenschrift.

*February 26, 1914.*

**Eugenics and Gynecology.**—Veits' lecture on this subject may prove to be a classic. He begins with an account of a chondrodystrophic dwarf, pregnant, in whom naturally normal parturition was out of the question. Cesarean section gave birth to a fine, healthy boy. On the very same day a girl of statuesque beauty gave birth to a dead anencephalus. An outsider was struck by the logic of the coincidence, which would have passed unnoticed in a large clinic, and it became apparent that the opportunities of the obstetrician in the direction of eugenics were superior in character. In the first place he has the opportunity of recognizing tuberculosis in the newly born—in such cases as have not undergone therapeutic abortion. If a woman is known to be tuberculous, she should be sterilized or at least if pregnant, submit to interruption of pregnancy. All these measures belong to the "eugenic sterilization" of Hirsch. The taint of epilepsy and imbecility has not yet been cleared up in full. The author has seen children of pronounced epileptics who possessed a high degree of mental excellence with no suggestion of epilepsy. The entire progeny of epileptics does not show any general inferiority. The same may not apply to the imbecile, for data are absent. It is true, however, that in a sound stock, an idiot may be born. This is explained apparently by heredity. Whenever the entire family tree can be traced, there will be found as equivalents, malformed children, cretins, etc., among the ascendants. In certain families chronic alcoholism in an ascendant is made to account for degeneracy in the progeny. The mere fact that a single descendant shows the taint is not sufficient to condemn the entire race. On account of lack of space an abstract cannot do justice to this long article, which could readily be expanded into a brochure.

**Prolonged Latency of Syphilis.**—Stern concludes his article on this subject. He arrives at various conclusions. Thus a single inunction cure will render 10 per cent. of all patients sound, as measured by absence of relapses. This takes no account of the Wassermann reaction which would no doubt reduce this 10 per cent. Lexer obtained an almost exact reversal of these percentages, for only 9 per cent. of prostitutes showed relapses after an intensive inunction cure. We must remember that in but a small percentage of infected do secondary relapses occur as far as the skin and mucosæ are concerned, because the spirochete has an overwhelming preference for the viscera. But a spot of irritation in the body may cause the appearances there of a virulent spirochete focus. The author has seen broad condylomata on the genitals of prostitutes from five to eight years after infection. Many old authors are quoted freely, and their finds given the same status as those whose opinions rule today. The final conclusions based on old and new matter are naturally somewhat paradoxic. Thus at least 50 per cent. of all syphilitics show no true secondary manifestations. Of the other 50 per cent. a large number are really tertiary. The quaternary lesions are especially liable to appear in subjects who have had no secondaries. Intensive treatment with Hg can reduce the relapses from 9 per cent. to 15 per cent. To control relapses is not to cure the disease. Syphilis is an "internal" disease as a rule.

---

**Case of Toxic Polyneuritis Due to the Virus of Poliomyelitis.**—F. E. Batten reports the case of a man, aged 20, who had an acute attack of "influenza" in August, 1898, when aged 5. This was followed by paralysis, and he was in the Children's Hospital, Great Ormond Street, suffering from a condition which was variously diagnosed as peripheral neuritis and poliomyelitis. Pain and tenderness were a marked feature of his illness, but he never had any loss of sensation. The boy slowly recovered, and now, fifteen years after the illness, presents a dwarfed appearance, being only 4 ft. 2 in. in height. He has a marked lateral curvature of the back, a general wasted condition of the legs and arms, but with no such local wasting of muscles as is commonly seen in most cases of poliomyelitis.—*Proceedings of the Royal Society of Medicine.*

## Insurance Medicine.

**The Need in Our Medical Schools of a Practical Course of Instruction in Life Insurance Examining.**—An insurance company must depend so absolutely upon the integrity and ability of its medical examiners that their selection is necessarily a problem of the greatest importance, and, while the methods of choice vary very much, there is unanimity of effort on the part of all companies to create a corps of well-trained examiners, and comparative efficiency once attained, to preserve it by a constant weeding out of the inefficient. Dr. C. T. Gaillard, in a paper on this subject, makes a plea for a systematic course of practical instruction in life insurance examining as a part of the curriculum in our medical schools. That such instruction is sadly needed is realized by all those who encounter and suffer from the raw work of an untrained examiner, and he expresses astonishment that so few medical colleges have recognized the advantages which might be derived by their graduates from such a course.

A few colleges do include a course, but the instruction is in general most inadequate, the subject being treated in a broad way in a short course of didactic lectures. Gaillard considers that the course should be made a practical one, which would make the graduate a more or less experienced examiner. In order to do this, the following few points should be thoroughly taught the undergraduate, preferably in his senior year:

First, the student should be taught the absolute necessity of rigid care in seeing that each and every question on the blank is answered. This is of utmost importance to the Home Office and also to the agent, who has a right to expect a quick action in a good case. The omission of a single "yes" or "no" requires a letter to the examiner, and the policy cannot be issued until his reply is received. Secondly, prompt replies to all correspondence from the Head Office is of vital importance. Failure in this respect allows of the delay in issuing a policy, or competition to step in and secure the applicant, or the change of mind of the applicant, disgusted through waiting.

The next most important point for the examiner is the ability to obtain a clear and correct personal history of the applicant. This gift is almost intuitive with some examiners, but is also the result of good training and experience. Training would teach the student the error of lengthy explanations of non-essentials, while, on the other hand, he would learn what details of history, etc., would require definite and specific information. To be practical and interesting to the student, he should be required to make actual examinations, using the blanks of the various companies so that he may familiarize himself with the different kinds in use. These blanks should be corrected by the lecturer and errors pointed out to the whole class. This course would be in no sense one in physical diagnosis, as that branch should be acquired in the regular course, but the student would thus learn how to use his general medical knowledge in a practical way for the real insurance work he may be called upon to do.

Gaillard insists that this course should be included in the curriculum of every medical college, as competition for appointments as insurance examiners is always keen, and the recent graduate's first effort toward increasing his income usually takes the form of making application for such appointments. His chances for appointment are immeasurably greater when he is able to show that he has received a practical course of instruction from his medical college. It is simply a business proposition of giving the preference to a partially trained man rather than to one wholly lacking in experience, taking it for granted that other professional training has been equal.

Considering the financial end of the question, it is estimated that insurance companies pay to the medical profession over six million dollars a year, which is earned by the examiners in the field and does not include the salaries of Home Office officials. This money is easily earned and is a most welcome addition to the income of a young physician, and the companies have a right to expect in return honest, intelligent and faithful service. That they do not receive it is another reason for this plea for instruction in medical insurance work for the undergraduate.—*Lancet-Clinic.*

**Cardiac Disturbances of Nervous Origin.**—Hoeflmayr states that in 1895 he recommended for insurance a risk with slight enlargement of the right heart, and an intermittent systolic murmur at the base. The medical director of the company protested, and a distinguished referee sustained the author. About a year later the latter's view was upheld by normal heart finds. Fifteen years later the author looked up the risk for self-satisfaction. The heart was normal in size and position. There was a slight initial systolic murmur, both on lying and standing. Pulse on standing, 100. General slight tremor, very nervous. Patient a mountain climber, taking prolonged tours without subjective or objective difficulties. Several other cases are given, which tend to emphasize the difficulty of differential diagnosis between organic and functional cardiac disorders. In one type of case serious symptoms of organic disease are found later to have vanished. There is, however, no means to foresee whether they will vanish. The author quotes freely from several standard writers on this subject.

When a number of components can be isolated—syphilis, alcohol, severe physical labor, athletics, previous history of heart disease—the chance of functional amelioration is slight. The author's conclusions are based on the results of Erben's method of procedure for the diagnosis of nervous heart. If a man squats deeply, with head inclined forward, the pulse after five or ten beats suddenly slows up. After about ten prolonged diastoles, the heart irrespective of posture, the beat slowly becomes more rapid and attains a frequency beyond the original. Latter repetitions of the test may give better results. The phenomenon may be more clean cut if some twenty deep knee flexions have been practised beforehand to cause acceleration of the pulse. Erben has tested this resource for ten years, and has found that in many cases it means a nervous heart only, which will not become organic. A gradual slowing of the pulse is physiological only. —*Blätter für Vertrauensärzte der Lebensversicherung*, Nov.-Dec., 1913.

**Informing the Unsuccessful Applicant of the Cause of His Rejection.**—In an address before the Life Underwriters' Association of New York on March 24, Dr. Oscar H. Rogers, medical director of the New York Life, said that when an insurance company rejected the application of any one for a policy the applicant should be informed of the reason for the rejection so that he might take advantage of the knowledge to improve his health.

# Book Reviews.

Radium Therapeutics. By N. S. Finzi, M.B. (Lond.), M.R.C.S., L.R.C.P., L.S.A., chief assistant in the *x*-ray department, St. Bartholomew's Hospital. Price, $2.00. London: Henry Frowde and Hodder and Stoughton; New York: Oxford University Press, 1913.

The newspaper notoriety which the alleged therapeutic powers of radium have recently received renders this small volume especially timely because of the judgment and extreme caution with which the subject is handled. It furnishes a wholesome check to the belief in the panacea-like qualities which radium is popularly supposed to possess. The introductory chapter offers a very satisfactory résumé of the more important physical qualities of radium and its radiations. In view of recent statements, it is interesting to note that the writer gives a diagram for the arrangement of an electromagnet by which the alpha, beta, and gamma rays of radium can be separated for experimental purposes, but points out that practically this method is limited in its application. He does not, however, call attention to the well-known fact that we have no means of separating the action on the tissues of the gamma and beta rays, because the beta rays are changed when they impinge on any substance into secondary gamma rays and these again are altered into secondary betas. It is, therefore, impossible at the present time to decide whether the action of radium on tissues is due to the beta rays or to the gamma rays or both. He also does not insist sufficiently upon the necessity for accurate quantitative determinations of the amount of rays in order to judge whether they are stimulating or destructive. The mere exposure of tissues growing *in vitro* to the gamma or beta rays will either stimulate or check growth according to the quantity and time of application, though most of the investigators who have worked on the subject so far seem to have been utterly oblivious to this important fact. The second chapter is devoted to the internal administration of radium and its emanations; the third, to the histological effects of the rays of tissues; the fourth, to apparatus and methods of application; and the remainder of the book to treatment. In this latter portion there is a certain vagueness of expression which is characteristic of a good deal of the radium literature. "Often" and "sometimes" occur very frequently. On page 75, for example, the author states that squamous-cell epitheliomata while they do not respond very readily "can be got rid of with a fair degree of certainty in early cases." On page 85, he states that "On the whole, squamous epithelioma does not react well." Any one who has seen the rapid growth of epitheliomata of the lip under the stimulating action of radium will agree that squamous-cell epithelioma of the ordinary type is not within the scope of radium therapy. The author also calls attention to the fact that tumors of the same morphological type may vary in their reaction to radium. This is the crux of the whole situation. In all tumors surgical removal should be the first step, and radium should be used only when operation is refused or on recurrent nodules, because it is impossible to foretell either clinically or microscopically which form of tumor will react favorably. Another point which it is well to remember is clearly brought out, that the application of 100 milligrams of radium bromide for one hour is much more effective than the application of 10 milligrams for ten hours. The great danger in the present state of radium investigation is that small and untested amounts of radium are used which act only in a stimulating way on the tumors. Only a few of those working on the subject of radium therapeutics have sufficient radium to obtain satisfactory results.

Surgery of the Abdomen. In Two Volumes. By John B. Deaver, M.D., Sc.D., LL.D., and Astley Paston Cooper Ashhurst, A.B., M.D. Vol. II.—Surgery of the Gall-Bladder, Liver, Pancreas, and Spleen. With 52 Illustrations. Price $5.00 net. Philadelphia: P. Blakiston's Son & Co., 1913.

The present volume completes the work of these two authors on the surgery of the upper abdomen, the first volume of which appeared about four years ago. In addition to the authors' personal experience in this field of surgery, they have incorporated a thorough review of all the more recent sources of information in this important department. The contents include chapters on the surgical diseases of the biliary tract, the gall-bladder, and bile ducts, and the liver. The pancreas and the spleen are considered in several additional chapters, and the concluding portion of the book is devoted to the technique of operation. In the preparation of the abdomen before operation, the authors have become converts to the iodine method, although they fail to record a warning against the accidental contamination of the peritoneum with the iodized skin. Not only the common, but the more unusual operations involved, are carefully described. The book may be regarded as the final word in the surgery of the upper abdomen, written by two men who are particularly well qualified for this task. The book is very well printed and satisfactorily illustrated, and a complete list of references is appended after every topic considered.

The Surgical Clinics of John B. Murphy, M.D. Volume II, Number VI (December). Octavo of 186 pages; illustrated. Price, per year, paper, $8.00; cloth, $12.00. Philadelphia and London: W. B. Saunders Company, 1913.

In comparison with the preceding number this is distinctly inferior, although this does not mean that it will not well repay careful reading. This number takes up the following subjects: Tuberculosis of the lung; Production of artificial pneumothorax by injection of nitrogen according to Dr. Murphy's method; Bone cyst of the radius; Pyonephrosis, drainage; Exostosis of radius and ulna; Ununited fracture of the radius previously plated, transplantation of bone; Ankylosis of elbow; Laminectomy for tuberculoma of spinal column, with compression of spinal cord, kyphosis and lateral curvature, motor paralysis; Subcutaneous abscess following tuberculosis of the spine, aspiration and injection of formalin and glycerin solution; Undescended testicle in inguinal canal; Cholelithiasis, stones in common duct, with intense jaundice; Metastatic carcinoma of femur; Traumatic sarcoma of femur. Then follows a list of 149 cases operated on and demonstrated during the week of the Clinical Congress of Surgeons of North America, and the index to Volume II. The discussion of the surgical treatment of pulmonary tuberculosis is especially timely in view of the renewed interest that is now being taken in the subject. In making the diagnosis of pyonephrosis, Murphy discusses briefly tumors of the kidney and calls attention to the statement he made about ten years ago that there was "no authentically recorded case of true *sarcoma* in the kidney that had survived beyond two or three years without a return of the disease either *in loco* or in the other kidney." Thus no one should remove a sarcomatous kidney because the patients will average more than that period of life if they are let alone. The last two subjects on the list were discussed at a students' clinic and, in our opinion, should have been condensed at least one-half for publication. The question and answer process is instructive to the student, but a waste of time for the men who read these Clinics. The editor himself appreciates this point and promises that it will not occur again.

The Human Body and Its Enemies. A Text-book of Physiology and Hygiene and Sanitation, by Carl Hartman, B.A., M.D., Instructor in Zoology, University of Texas; and L. B. Bibb, B.A., M.D., attending physician Austin Sanatorium. 247 illustrations. Price, 84 cents. Yonkers on the Hudson: World Book Company, 1913.

The most important thing to emphasize in school physiologies is no longer anatomy or physiology but hygiene, particularly the parts dealing with the prevention of germ diseases. This text-book complies with the new ideas, not minimizing any of the phases of the subject but preserving the correct proportion among them. A summary of the most important points and questions is added at the end of each chapter. Numerous experiments easy to perform are scattered throughout the book. The illustrations are numerous and have a pedagogic value.

First Book of Health, a Text-book of the Personal Hygiene for Pupils in the Lower Grades, by Carl Hartman, B.A., M.D., Instructor in Zoology, University of Texas, and L. B. Bibb, B.A., M.D., Attending Physician Austin Sanatorium. Yonkers on the Hudson: World Book Company, 1913.

This book attempts to inculcate correct habits of living in the very young in simple language, intelligible to school children in the lower grades. It puts the pupil in possession of some of the great principles of sanitation, teaching him to be cleanly in person and how to escape from diseases that he himself has the power to avoid.

Diseases of Women, Medical and Surgical Gynecology. By Charles A. L. Reed, A.M., F.C.S., M.D. With Four Hundred and Forty-eight Illustrations in the Text. New York and London: D. Appleton & Co., 1913.

The preface of a new work is necessarily of interest to the reviewer as the author of the work usually employs this means to place before the reader his particular purposes in writing the same. The preface to Dr. Reed's very interesting work presents his purposes more clearly than is usually the case, and one cannot do better than to abstract the same and then venture to submit conclusions as to whether these purposes have been fulfilled. The book is stated to have been written exclusively to meet the demands of utility, and the writer believes that a practitioner, whether general or restricted, demands primarily a knowledge of the various pathological conditions peculiar to women, then the ability to determine the diagnosis of the particular case in hand, and finally a knowledge of what to do for it. A teacher of gynecology requires as a reference book for himself and as a textbook for his students, a work that is at once systematic, direct, and brief, without being synoptic; that is comprehensive without being discursive. A writer on gynecology needs a convenient text covering the particular status of the subject at hand. Dr. Reed has set himself to meet all these requirements in the present volume. His first departure is an omission of elementary anatomy, pathology, and bacteriology, all of which it is presupposed that the reader is familiar with. The usual bibliographical tables are also omitted for the reason that they can be found in a more satisfactory form in the *Index Medicus*. In addition to the topics usually considered under the head of gynecology the book also includes the surgery of the rectum, certain obstetrical operations, and surgical conditions of the kidney and ureters. The author states that he has made no effort to write a monograph containing his individual opinions on every topic considered, but, on the contrary, to give the actual status of each subject as it existed at the moment of writing. The judgment which he has been compelled to exercise may be stated to be a very satisfactory one. Diagnostic measures as they exist to-day are emphasized because of the conviction that careful training in this respect is not sufficiently developed in the profession. Medical and hygienic measures are featured in the initial stages of many cases belonging to the category embraced in this work, and the author is careful to insist on a sharp line of distinction being drawn between what may be classified as medical and surgical conditions. Dr. Reed is to be commended for his insistence that prolonged medical treatment in cases that require surgical measures often amounts to criminal negligence, the responsibility for which must be defined in courts of law. In recommendation of the fact that gynecology is a department of surgery, the author has described in detail something over two hundred operative procedures in which he has tried as nearly as possible to place the knife in the hands of the reader and then to tell him how to use it by directing him through each succeeding step. He is careful to state, however, that the presentation of such details does not warrant any one to undertake these procedures unless he has been properly drilled and apprenticed in surgical technique. The author is to be commended for calling attention to the fact that a practical knowledge of gynecology cannot be gained from any book, but must be acquired by actual observation and apprenticeship.

A careful examination of the book shows that the task which the author has set himself to do as outlined in his preface is satisfactorily carried out, both in the text and illustrations. Dr. Reed's own contributions to gynecology are so extensive that they occupy many pages, but credit is given wherever it is due to other workers in this field. The application of the originator's name to so many operative procedures may perhaps be questioned and descriptive terms would be more satisfactory than the application of a particular operator's name to some definite operative procedure. For example, in the description of cesarean section which we find in an excellent chapter on "Surgical Intervention in Dystocia," Cameron, Sänger, and Mann are all distinguished by having their names applied to certain procedures which might have been labeled much more satisfactorily in other ways. Reed favors the abdominal cesarean operation in preference to the vaginal route, which seems a strange admission by a gynecologist, in view of the fact that those who advocate the latter procedure are particular in asserting that a gynecological training will better fit one to carry it out. There is a definite field for this operation in cases where the abdominal cesarean is inapplicable, and although its use is restricted it is deserving of more attention than the author is inclined to extend to the same. The author fails to note the high abdominal incision as practised successfully by A. B. Davis. In the section on plastic operations the various accepted procedures are most satisfactorily presented and afford an excellent idea of the treatment of this class of cases. Among them considerable interest attaches to the procedure for correcting flexions of the uterus by excision of a wedge-shaped segment from the anterior or posterior wall by the abdominal route. A similar procedure by the vaginal route has been suggested by Coffey and others. A description of gonococcus infections is very commendable and the author gives to this important subject the attention which it deserves. The book contains a great many admirable features which should commend it to the practitioner and specialist. It constitutes a praiseworthy addition to American literature on gynecology and is worthy of the serious attention which the well-known abilities of the writer unquestionably command.

Bibliography of the Education and Care of Crippled Children. A Manual and Guide to the Literature Relating to Cripples, together with an Analytical Index. By Douglas C. McMurtrie. First Edition. New York: Douglas C. McMurtrie, 1913.

The importance of a volume of this kind can be fully appreciated only by one who has vainly sought references to the literature pertaining to the education and care of crippled children. The author has performed an invaluable service to sociologists, physicians, charity workers, and educators in compiling all the available literature on this subject. The volume is divided into three parts. In the first part there are 432 entries arranged alphabetically, according to the authors' names. In the second part there are 292 anonymous entries, also arranged alphabetically, according to the main subject matter. The third part comprises an analytical index, in which all the articles recorded in the first two parts are again referred to by number, entries being indexed by subjects, geographically, and by proper names, either of authors or of persons mentioned in the titles or annotations. The volume is handsomely printed and bound and fittingly represents a labor of love.

The Healthy Marriage. A Medical and Psychological Guide for Wives. By G. T. Wrench, M.D., B.S., (Lond.), Past Assistant Master of the Rotunda Hospital, Dublin. Price, $1.50 net. New York: Paul B. Hoeber, 1914.

This small book is designed for the instruction of married women and serves its purpose fairly well. The first chapter on The Value of Marriage is perhaps the most interesting. The subjects of Hygiene, Menstruation, Pregnancy, Labor, and Lactation are discussed in a clear, non-technical fashion and will be easily understood by the layman. The author makes one statement to which we must take decided exception. On page 110 he says, "The chief pollution of the air that is to be feared by a lying-in woman is that from drains, for such air can, it has been proved, be the cause of serious lying-in or puerperal fever." To find such a statement in a book published in 1914 is astounding to say the least. If any one thing in all medicine has been definitely proven it is the infectious nature of puerperal fever. The author's apparent recommendation of the purchase and casual use of such drugs as phenacetin and veronal without a physician's orders certainly should not be encouraged.

Moderne Radium and Thorium Therapie bei der Behandlung der Geschwülste, der Gicht, der rheumatischen Erkrankungen, der Neuralgien, und der Blutkrankheiten. Von Dr. Med. Adolph Bickel, Professor an der Universität, Berlin. Vortrag, gehalten on Fortbildungskurs, für praktische Aertze am 13 November, 1913. Price 1 Mk. Berlin: August Hirschwald, 1914.

This brochure discusses the physical, biological, and medical aspects of radium and thorium. Particular stress is laid upon the nutritive, functional, and formative effects of the rays on cell life of normal and pathological tissues.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held February 19, 1914.*

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR.

### SYMPOSIUM ON THE PSYCHOPATHIES OF CHILDREN.

**The Education of High-Grade Defectives.**—Dr. B. SACHS presented this communication in which he declared that if medical men would bestir themselves, not only to offer aid in the solution of the problem of the education of defective children, but to first become acquainted with the efforts which had already been made by our public school authorities, some good might result. The force of medical opinion was needed in order that a constructive program might be carried out satisfactorily in this city. Dr. Sachs said there might be some doubt as to the duty which the public school had with reference to the low-grade defectives, the imbeciles, and the idiots, but there could be no doubt in regard to the high-grade defectives, who often differed but little from the supposedly normal child. Unusual and unnecessary stress had been laid upon the relation of crime to mental deficiency. The essayist had found that there was no need of putting this additional stigma of immorality upon families that were unfortunate enough to have defective children; in his opinion hereditary and prenatal influences bearing upon the development of criminals could be largely neutralized by proper environment. In this field there was a vast opportunity for the social worker. So far as possible the attempt must be made to secure proper environment for such children as came under the notice of the public authorities. In the entire movement for the care of defective children there must be hearty cooperation between the teacher, the social worker, and the physician. After calling attention to the work that had been accomplished by our school system Dr. Sachs said that it was very evident that the public school system had the entire machinery for the proper investigation of these defective children and for the means of placing them under proper supervision. In the ungraded class the children with varying degrees of mental defect were grouped together and one teacher was supposed to handle the entire class. As there was as great a difference in the mental powers of the high-grade defectives as in that of normal children it was easy to understand what an unfruitful task was the endeavor to educate all in the same class. If the ungraded class was to be the solution of this problem they must at least insist that there be different grades of ungraded classes. The ideal plan would be to have special schools scattered throughout the various districts in the city for the training of defective children. The school authorities had insisted that there would be serious opposition to the creation of such schools and that the public would resist sending their children to such schools upon which a certain stigma would rest. The Board of Education reported that special schools of this kind in Pennsylvania and Massachusets had to be abandoned, and it was doubtful if this objection should be encouraged. A change in name would often change the attitude of the public, as was seen by the fact that many did not hesitate to send a member of their family to a sanatorium who would object to sending the same individual to an asylum. If auxiliary schools were created, and if they were to include classes not only for the purely mental defective but also for those who had some other infirmity, say, for stammerers, for the deaf, and possibly for blind children, the stigma resting upon such auxiliary school would not be so keenly felt by the community. A moderate estimate seemed to indicate that there were fully 3½ to 4 per cent. of the school population needing some form of special training. The high-grade defective differed only slightly from the normal; there was a very gradual transition from the child who had normal powers of perception, or vision, of reasoning, and of memory, to the child who was slow of perception, chronically defective in its judgment, and somewhat slow in memorizing. The high-grade defectives were at a special disadvantage at the present day because of the modern methods of instruction in which the child acquired a knowledge of reading, writing, and spelling more by visual and auditory impression than by the development of memory, as was the case by the older methods of education. Many a child who was slow of perception could much more readily develop the power of memory, and yet the modern teacher of the normal child had no sympathy for the older methods of instruction. Curiously memory seemed to have fallen to a rather low degree in the estimation of the teachers, and the speaker said he could not see why that should be the case. This brought up the question of competent teachers—a very vital one. The teachers who were to care for defective children must necessarily be instructed in special methods and must possess special innate qualifications, so that among each class of teachers there could necessarily be only a limited number who would be at all fitted for this special work. It required an enormous amount of patience and a power to analyze the mind which few teachers and few individuals, on the whole, possessed. Dr. Sachs reviewed a case which illustrated the fact that frequently a speech defect was responsible for a teacher considering a child as mentally defective when in reality his mental faculties were quite up to the normal. In connection with speech defects the correctly called psychic speech defects as well as the mechanical should be considered and provided for in the special schools. Stammerers and all those who had similar defects should be treated in these schools. The high-grade defective child was at a great disadvantage because he was placed in a class with the lower grade defective or the idiot, and after all his mind and brain matter were not very much inferior to those of the supposedly normal child, and putting him with the low-grade defectives was doing him more harm than placing him among normal children. Therefore, if there was to be an ungraded class in the average public school, it should answer the purpose for the high-grade defective. If the public schools would care for these high-grade defectives they would be doing a very important duty because from this class useful citizens might be made, and with patience these minor defects might be overcome. Dr. Sachs, in closing, urged the medical men to stand back of the Board of Education in urging that the proper amount of attention and money be devoted to this special form of instruction.

**A Comparison of Certain Methods of Primary Education of Children with Reference to Their Value in Lessening the Liability to Psychoneuroses.**—Dr. JAMES J. PUTNAM of Boston read this paper in which he dwelt upon the importance, and also the difficulty, of training children from infancy onward, and during infancy, in such a way as to prevent them, so far as possible, from developing neurotic tendencies in later years. The carrying out of this difficult task devolved primarily on the mother, secondarily on the teacher; and the important thing for which physicians should strive was that these two classes of persons should be themselves trained to know more in detail about the psychology of infants and young children, on the one hand, and on the other hand to have strong and definite views about the goal of education at its best. A knowledge of childhood was not to be obtained except through an acquaintance with the principles and facts discovered or emphasized through the psychoanalytic movement. Young children began to find themselves, from birth onward, exposed to a double tendency—namely, that of seeking their own pleasure or their own advancement, in and for themselves alone, or that of recognizing, even dimly, that their lives belonged in part to the community, and could not be developed properly except in relation to the community, in an actual and an ideal sense. While, in consequence of this tendency to be drawn into paths that were not the best, the child was exposed to constant danger, yet nature was fortunately generous in offering more than one opportunity to every one to work out his development with some prospect of success. Parents and teachers should not, therefore, be too ready to assume that threatening symptoms necessarily mean a seriously bad outcome. Each person carried in himself an almost inexhaustible elasticity, and a longing, often misunderstood, toward some better course than that which showed itself at first. Referring more especially to the means of overcoming the dangers to which the child was exposed, on the one hand, and of promoting the best sort of forward development on the other hand, Dr. Putnam spoke of the importance of gaining an adequate knowledge of the psychology of childhood, as developed through psychoanalysis, and also an adequate knowledge of the real obligations and opportunities of the adult, and of the manner in which ordinary faults of character, which were practically nervous symptoms in disguise, interfered with the carrying out of these obligations. If the mother could learn to know something of her own childhood, and through this could acquire patience and recognize the importance of a

sympathetic attention to her child's intentions and troubles, she could put herself in a position to enable him to utilize his first mistakes as a means toward something better, while at the same time avoiding the blunder of encouraging a harsh unsympathetic repression on the child's part. As regarded the second portion of the advice, Dr. Putnam spoke at considerable length of the value of methods of training of which the kindergarten system of Froebel was the best example and type. The essential element in this system was that it encouraged the recognition, on the part of each child, and eventually of each adult, that he was at once a constituent part and a representative of the community, taken in a constantly wider and wider sense. The child could not be taught directly to entertain ideas of this sort, but if the mother entertained them, and had made them an integral part of her own life, the child would tend to become gradually imbued with corresponding feelings. To teach the child in this way meant to convey to him religious ideas in the best and simplest form. Psychoanalysis was of value here also, because its scrutinizing tendency laid bare false and sentimental attitudes which might be called religious, but which had little in common with religion or philosophy, in the best sense. With reference to the details of the psychology of childhood, as brought out through the psychoanalytic method, Dr. Putnam referred, among other sources of information, to a book by Dr. Von Hug-Hellmuth, called "Das Seelenleben des Kindes." Psychoanalysis itself should be considered as a phase of education, and pursued as being a partial science of human motives, and needed to be viewed on the background of a final nd inclusive science of human motives. The essential point then in the training of the child was that every mother and every teacher should, on the one hand, learn to know more in detail about the child's dangers, and on the other hand, should have far higher standards than were at all uniformly prevalent with reference to ethical needs and possibilities, in order that they might impart these to the child, not so much in words as through an unseen influence. The child should be regarded then, not alone from the side of his defects and faults, and as a troublesome member of society whom it was our duty to correct, but as a being animated by some rays of an immense power which we should learn to recognize and foster. But at the same time it was not enough to say that the education of the child should be conducted, for example, in a religious spirit, for this spirit needed the critical pruning and scrutiny that only an adequate psychoanalytic method of illumination could supply.

SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, Held January 27, 1914.*

DR. ASA B. DAVIS IN THE CHAIR.

**Report of Two Cases of Ectopic Pregnancy. Presentation of Patients and Specimens.**—Dr. ALFRED M. HELLMAN made this presentation. He stated that the patients entered the Lebanon Hospital the same day and the specimens obtained from them were unusual.

CASE I.—This patient was 30 years of age and her last period was ten weeks before her admission to the hospital. She had been married nine weeks. Four weeks before admission to the hospital, or about January 3, she began to stain slightly and had cramps in the lower abdomen. This stopped but began again two weeks later and continued up to the time of admission. At 8 A.M. of the day of admission she was seized with sudden dizziness, blurring of vision, and fainting. She presented the usual symptoms of ruptured ectopic pregnancy. Upon the arrival of the patient at the hospital, a median incision under ether anesthesia, and a saline infusion were started at the same time. The left bleeding tube was easily found and tied. The patient's condition rapidly improved during the operation. The rupture in the tube was so close to the cornu of the uterus that it was necessary to resect a large fibroid which was pinned to the uterus. As it was impossible to arrest the bleeding from the base of the fibroid a simple typical supravaginal hysterectomy was done. The patient was returned to bed and given another infusion. She made a rapid and uneventful recovery. The specimen was a uterus with multiple fibroids, the largest one arising at the left cornu and right next to the point of rupture of the ectopic.

CASE II.—This patient, 26 years of age, was admitted to the hospital with the following history: She had been married four years, had two children, the youngest eight months of age. Her labors had been uncomplicated. After her last labor amenorrhea persisted for six months. On November 10, bleeding occurred and continued until she was admitted to the hospital. On December 15, when riding on a street car, she was severely jolted and thrown, when she was immediately seized with severe cramps in the lower abdomen and had vaginal bleeding. One week before admission the cramps again became worse and from that time defecation was extremely painful. When she was admitted on January 3 she had a temperature of 106 F., tenderness over the lower abdomen, and exquisite tenderness and a rounded mass in the cul-de-sac of Douglas. The temperature rapidly became normal and four days later the specimen presented was removed, and the patient made an uneventful recovery. The specimen was a distended tube which had ruptured along its upper border though the opening was closed by clots. The ovum was intact and adherent to the posterior wall.

**Report on a Case Presenting Three Ureters; One Opening Extravesically. Operation Followed by Relief.**—Dr. HENRY DAWSON FURNISS reported this case. The patient was a young woman, 20 years of age, first seen by him in June, 1913. She stated that ever since she could remember she had been constantly wet with urine day and night, and that rest made no difference. She complained of no other symptoms. A ureter opening extravesically was suspected. The patient was given indigo-carmine intravenously and the vagina and vestibule packed with wet cotton. After fifteen minutes it was seen that the cotton over the urethra was faintly stained. A small opening was found just underneath the urethral meatus. This could be catheterized only one inch and a half, and from it the catheter seemed to run to the left. Cystoscopy showed a normal bladder and ureters discharging normally. A diagnosis of supernumerary extravesical ureter was made. At the Post-Graduate Hospital, June 28, 1913, under ether anesthesia, the supernumerary ureter was catheterized for four inches. An incision was made with scissors into the mucosa covering the under surface of the urethra over the catheter. Unfortunately the incision went into the ureter, which was here dilated to the size of a large lead pencil. A sound was then passed into the bladder and the bladder mucosa and the mucosa of the sac were united with fine catgut in such a way that the distal end was obstructed. Thus the ureter was made to enter the sac and from the sac to the bladder a fistula was formed. The original plan was to dissect out the ureter for a distance of one and one-half to two inches; then make an opening into the bladder from the bed from which the ureter was dissected, and through this to put the ureter into the bladder. The change in method of operating was due to the dilatation of the distal end of the ureter, which thinned out the ureteral wall and to the thinness of the mucosa covering the ureter. After the operation there was no leakage for two days. The catheter was removed from the bladder on the third day and the patient began to wet herself as usual. On July 11 the following operation was done: The ureter was dissected backward for one and one-half inches. The ureter increased in size toward the renal end and was about one-half the thickness of a led pencil. A suture was placed through the end of the ureter, and a sound was passed into the bladder which was made to bulge the bladder wall backwards and to the left, and over this a small incision was made. The suture was held to the sound and the ureter pulled into the bladder where it was held with one suture through the bladder and a part of the ureter. The suture that pulled the ureter into the bladder was sutured just below the clitoris. A permanent catheter was left in the bladder for four days. Following the operation the patient developed a marked cystitis, which responded readily to irrigations of nitrate of silver. Since this operation there had been no leakage of urine and the patient had been entirely relieved of her troublesome condition.

**A Case of Reported Adenocarcinoma Cured by Curetting.**—Dr. HERMAN J. BOLDT read this report. The patient had consulted him the day after she had left Dr. Ladinski's care. She wanted to know whether a hysterectomy was necessary, because she had been told that she had cancer. After putting himself in communication with the pathologist Dr. Boldt said he had failed to get a copy of his report, or the specimen, or

the slides upon which the diagnosis had been based. Not finding, upon the most careful examination, the slightest subjective or objective evidence of carcinoma, he had proposed a curettage and an additional examination of the scrapings. About two weeks later, after the report on the examination of the second curretting specimens had been received, Dr. Ladinski's pathologist lent him the slides which were made from the block in which, he said, the scrapings from the patient were embedded, and he was astonished to find an adenocarcinoma, far advanced, as was indicated by the slide on exhibition. On the second slide was an area of carcinoma not much resembling the character of the cancer observed on the first slide. A study of the sections failed to show a transitional stage. Other competent experts had also failed to find a transitional stage. All stated that it was not an early stage of adenocarcinoma. So Dr. Ladinski's case, considering all features, must be considered unique. Dr. Ladinski was to be congratulated on being so singularly fortunate as to have, as seemed evident, the first case which had been cured of advanced adenocarcinoma by curretting for diagnosis. There had been a few cases of adenocarcinoma reported cured by curetting for diagnosis but they did not resemble this case. It was evident that the disease was not in the early stage; it had transgressed, as one of the sections showed, full into the muscularis. Whereas serial sections of the curettings obtained two weeks later from the same patient, and the scrapings were done very thoroughly, not missing any part of the endometrium, showed practically a normal mucosa. In order to illustrate how unusual Dr. Ladinski's case was Dr. Boldt submitted the written reports from two pathologists, whose ability and competency could not be denied, Professor William H. Welch of Johns Hopkins, who had no superior living to-day; and Dr. Noujean, of the Practitioners' Laboratory, who had experience under von Recklinghausen and Baumgarten beside clinical experience as assistant in the leading gynecological clinics of Europe. Some other experts in pathology expressed the opinion that the case was so "unparalleled that it was more natural to suppose that a mistake had been made in the specimens, which might occur and repeatedly had occurred, no matter how carefully laboratory work was conducted." But in this particular instance this seemed impossible from what the pathologist who examined Dr. Ladinski's specimen said. Dr. Boldt recalled another instance, seen in consultation with Dr. Ladinski some seven or eight years ago, under somewhat similar circumstances. That patient was seen by the speaker three years later, and was in perfect health, despite the fact that her uterus had not been removed, because of Dr. Boldt's opposition, though it was asserted by Dr. Ladinski to be the seat of malignant neoplasm, and that the patient would die if the uterus were not removed.

Although only a few weeks had passed in this last case, yet a most careful intrauterine exploration, made on January 20 revealed nothing suspicious. If one could get a cure, judging entirely from the pathological report, from an ordinary curetting for diagnosis, it would seem that those—and the speaker said he belonged to that number—who insisted upon the desirability of doing a radical operation, in the early stages of carcinoma of the uterus, were subjecting their patients to an unjustifiable risk and their conception of cancer of the body of the uterus was faulty, and they ought to remodel their therapy in instances of malignant disease of the body of the uterus. Dr. Boldt then read the reports of Dr. William H. Welch and Dr. Victor Neujean, both of which concurred in finding absolutely no evidence of adenocarcinoma or other serious abnormality.

Dr. Louis J. Ladinski said that the question of pathological diagnosis in this case would have to be settled by the pathologists. He was glad that Dr. Boldt had reported the case in full, and that it would only be necessary for him to give the history of the case up to the time when Dr. Boldt had first seen the patient. Dr. Ladinski said that he took exception to the reference made by Dr. Boldt to another case, seen some seven or eight years ago by him at Beth Israel Hospital with Dr. Ladinski, as being similar to the case just reported. In that case Dr. Ladinski advised an exploratory curettage on a woman who had aborted and who bled profusely and persistently, in order to ascertain whether malignancy were present, and if present, a hysterectomy was proposed. When Dr. Boldt made a digital examination of the uterine cavity, he did not think there was malignancy; a curettage was then done, and as the specimen examined showed nothing abnormal a hysterectomy was not done. That case was not one of adenocarcinoma cured by curettage. The case reported by Dr. Boldt was seen by Dr. Ladinski at his office for the first time on October 7, 1913. She was 47 years of age, had been married twenty-two years, and had never conceived. She had menstruated regularly every four weeks, from one to five days, until two years ago, when the menses ceased for a whole year. For the past year, however, she had bled irregularly on and off. She complained of no pain. On examination the uterus was found somewhat larger than would have been expected in a woman who had never conceived and had begun the menopause two years ago. A small bleeding mucous polypus protruded from the os. This the speaker said he clipped off. As the bleeding continued in spite of several intrauterine applications of iodine for five weeks after the removal of the polypus, he had advised a curettage for diagnostic purposes. He continually assured the patient that the bleeding was not caused by any malignant disease, even when he had removed the tissue from the uterus. Much to his chagrin Dr. Eli Moschcowitz, the pathologist, reported that the scrapings showed adenocarcinoma. The patient was taken home to recuperate for a hysterectomy, when her relatives asked for a consultation with Dr. Coe, and he had concurred with the speaker as to the advisability of a hysterectomy. The patient then went to Dr. Boldt. The interesting feature of this case was the coincidence of mucous cervical polypus which marked the history and clinical symptoms of what would otherwise have been looked upon as almost pathognomonic of malignancy, so that the curettage was postponed for about six weeks. This case taught that with the suspicious history that was here presented it was imperative to take nothing for granted, but to do a curettage for diagnostic purposes. Had he performed a diagnostic curettage when the patient came to him she would have consented to a hysterectomy and would now be free from a uterus which was positively the seat of adenocarcinoma a few months ago, and should, therefore, be removed. As an instance that a case of adenocarcinoma could not be considered cured because the second scrapings done two months after the first did not confirm the presence of malignancy Dr. Ladinski read the report of a case reported before the Section May 25, 1911, and published in the *American Journal of Obstetrics and Diseases of Women and Children*, August, 1911.

Dr. Eli Moschcowitz said that in this instance a mistake arising from incorrect numbering of the slides in the laboratory could be excluded. The specimen could be definitely traced from the operating room to the fully prepared slide; moreover, no case of adenocarcinoma of the uterus came to the laboratory for many weeks before and after this incident. Dr. Moschcowitz defined what he understood by the terms "precancerous stage" and "early" cancer. He did not believe the term "precancerous stage" was justified. A tumor was either a cancer or not a cancer. He did not deny that there were predisposing conditions, but these were not cancer. He understood the term "early" cancer as signifying size rather than precise microscopic picture. The microscopic unit of every variety of carcinoma was the same, whether the cancer was small or large in size. It was, therefore, impossible from a given microscopic picture to determine whether a cancer was in the early or late stage. The fact that Dr. Ladinski's specimen showed extension into the musculature did not, therefore, necessarily prove that the carcinoma was advanced. This extension into the musculature was demonstrable in practically every case of carcinoma of the corpus uteri; indeed, he did not recall any case of carcinoma of the corpus uteri which was strictly limited to the mucosa. There was only one conclusion to be derived from the course of events occurring in Dr. Ladinski's case and that was that at the first curettage the entire carcinomatous area was removed. In the past few months four cases of similar nature had been reported in the German literature. Many pathologists to whom Dr. Moschcowitz had spoken related similar experiences, namely, that they had reported adenocarcinoma upon exploratory curettings, and examination of the uterus after hysterectomy showed no further traces of malignancy. Dr. Moschcowitz did not believe that Dr. Boldt was justified in reporting the case as "cured." . . . The case would be of even

greater interest if reported three years from now.

Dr. BOLDT, in closing the discussion, said that he had nothing to add about this case, but that he remembered the case referred to which he had seen seven or eight years ago. A hysterectomy was to have been performed on a certain day and the husband came to him and urged him to see the case and advise in regard to the proposed operation. He at first refused, but it was finally arranged that he should see the patient. Dr. Ladinski made the statement that he was going to do a hysterectomy as the condition was one of malignancy. Dr. Boldt said that from the clinical evidence he differed in regard to this diagnosis. There had been no profuse hemorrhage, only slight hemorrhage at intervals. He had suggested that Dr. Ladinski do a curettage and not a hysterectomy.

Dr. LADINSKI, in closing the discussion, said, in regard to Dr. Boldt's statement concerning the case referred to as occurring seven or eight years ago, he would like to ask Dr. Boldt to say whether scrapings had been made and whether a pathological diagnosis had been made before Dr. Boldt saw the case; furthermore, whether Dr. Ladinski had advised a hysterectomy when a microscopical diagnosis had not been made. Dr. Ladinski declared that it was quite impossible that he could have advised a hysterectomy for carcinoma without a laboratory diagnosis of the curettings. That was not his custom.

**Two Cases of Congenital Absence of the Vagina.**—Dr. HERMAN J. BOLDT reported these cases. The first case showed absence of the vagina, a rudimentary uterine cavity, and cystic degeneration of both ovaries. The second case showed the anatomical conditions usually found in such cases, rudimentary uterus and tube, and ovary somewhat elongated and in cystic degeneration. In both of these instances a vagina was made by intestinal implantation, using a part of the colon. The results appeared to be successful, but he did not know about the function in the sexual relation. He had lost sight of the first patient and the second had been deserted by her husband because of the absence of the vagina and had not returned. Dr. Boldt felt sure that the result would remain perfect as it was a physical impossibility for contraction to occur with the normal mucous membrane.

Dr. HENRY DAWSON FURNISS said he had seen two instances of complete absence of the vagina, one of which had been operated upon. Two of the cases had come to the clinic because they were contemplating marriage and wanted to know if marriage would bring about the establishment of the menstrual function. In these two instances no evidences of genital organs could be found. In the case operated upon an attempt was made to line the vagina with skin flaps, but the result was exceedingly unsatisfactory. In his opinion the method used by Dr. Boldt was the one of choice.

**Report on a Case of Cesarean Section Followed by Hysterectomy for Dystocia Due to Fibroid in the Lower Uterine Segment.**—Dr. GEORGE W. KOSMAK reported this case and presented specimens and diagrams. He stated that the case was reported as an instance of absolute dystocia due to a hard fibroid mass which occupied the greater part of the pelvic inlet. The patient was 33 years of age, and married for the second time in October, 1912. She had never been pregnant before and her menstrual history was normal in every respect. Her last regular period occurred on February 14, 1913. During the last week in April the peivic tumor was diagnosed for the first time and the patient was advised to have her pregnancy terminated. She concluded, however, that she would try to carry the child to term. She was first seen by Dr. Kosmak on September 20, 1913, when the fetus was found to be about seven and one-half months. Vaginal examination showed the pelvis obstructed by a large rounded mass above which the fetal head could be distinctly palpated. The cervix was small, moderately softened, not dilated, and occupied a position back of the symphysis where it could be reached with difficulty. The patient was seen at regular intervals and the growth of the fundus followed. She was admitted to the Lying-In Hospital on November 27, the end of the pregnancy having been calculated for November 21. As the pelvic mass seemed firmly fixed and it was impossible to displace it a cesarean section was decided upon and the patient was operated upon on November 29, 1913. A hypodermic of ergotole was administered at the beginning of the anesthetic. In view of the necessity for doing a hysterectomy, the incision was made in the median line below the umbilicus and within three inches of the symphysis. On entering the abdomen the uterus was found to be irregular in shape with firm walls containing a number of fibroid nodules. The peritoneum was loosely attached over the entire anterior aspect of the uterus and the vessels on the surface were greatly distended. The incision in the uterus was made in the median line and the wall found to be at least two inches thick. The membranes were freed, the sac ruptured and the fetus extracted by the breech. It was readily resuscitated. The friable placenta was extracted completely together with the membranes; both showed decided yellow tinge. There were numerous large and small fibroid masses present over the entire segment of the uterus and the lower portion was likewise made up of a rounded fibroid mass which almost completely filled the pelvis. As the patient was in good condition a hysterectomy was decided upon. Owing to adhesions and the varicose condition of the surrounding veins it was not possible to save the ovaries. A supravaginal amputation was successfully done and the cervical stump then sewed over with interrupted chromic gut. During the early stages of the hysterectomy the patient's pulse began to go up and 1,000 c.c. of salt solution were introduced under the breasts. On the left side the descending colon was bared because of its adhesions to the uterus. This was carefully sewed over and gave no further trouble. The patient made a perfectly uninterrupted recovery with the exception of a slight pyelitis. Both she and the baby left the hospital in excellent condition. The case with the specimen shown demonstrated conclusively the inadvisability of waiting too long in the presence of this form of dystocia before resorting to radical operation. The question of doing the hysterectomy at a later time was answered by the favorable recovery which resulted in comparison with the possible sloughing and degeneration which might have occurred in this fibroid mass had it not been removed.

**Chronic Cystic Mastitis or Abnormal Involution of the Breast.**—Dr. PARKER SYMS presented this communication. He stated that little or nothing was known of the etiology of this condition. The histological changes were of such a variety that the disease had received a great many names, most of them indicative of some characteristics of the pathological changes; and these changes varied so much in different cases that an observer was very apt to give a name to the process depending on those changes which had appeared most prominent in the cases that he had studied. An incomplete list of the titles which had been given to this condition included chronic mammary tumor, cystic disease of the breast, or intraacinous cystic epithelioma, epithelial cirrhosis, interstitial mastitis, chronic cystic mastitis, nodular mastitis, fibroma mammæ tuberosum, cyst adenoma, mammary cirrhosis, cystic epitheliomata, papillary epitheliomata, chronic mastitis, mastitis chronica fibrosa, epithelial polycystoma, fibrous and glandular hyperplasia with retention cysts, senile parenchymatous hypertrophy, abnormal involution of the breast, mastitis of the menopause, chronic diffuse mastitis. The disease usually occurred after the thirtieth year in women who had borne children, in married women who had not borne children, and among single women who had not borne children. It also occurred in men. Owing to the fact that it occurred during the age period above cited it represented a change taking place in the breast during the actual cancer period. Owing to the remarkable changes which took place in the epithelium, and the fact that a very large proportion of these cases became cancerous, it was proper that it be considered as one of the precancerous conditions. Acute mastitis sometimes preceded the development of this chronic form, and it was doubtless an etiological factor in a small proportion of cases. There was little if any evidence to show that traumatism had acted as a causative factor in this condition. Being an inflammation it must be assumed that the phenomena were really a response to some form of irritation, either mechanical, bacterial, or chemical. There were some who claimed that all such hyperplastic inflammations were due to autotoxication. The essayist thought that it was more likely that they would find its explanation in the very unstable nature of the physiological functions of the gland. He reviewed the changes coincident with puberty, menstruation, lactation, and the menopause, which showed that the gland throughout life was subject to rapid evolutions and involutions. The epithelium was singularly unstable and

subject to change in both its quantity and its quality, and in relation to itself and the other structures of the gland. There was a singular analogy between his condition and the condition commonly known as senile hypertrophy of the prostate. Senile hypertrophy of the prostate was really a chronic cystic prostatitis. The two conditions were similar in their liability to transformation into cancer. From the names given to this condition it would be seen that some authors considered it to be purely an inflammatory process; others considered it entirely hyperplasia; while still others had seen only the evidence of tumor formation. Probably no one name in the entirely list given gave a sufficiently comprehensive idea of the condition except the indefinite one of Warren, namely, abnormal involution of the breast. Whitney had probably come nearer to it and his title would have been correct had he amplified it thus, chronic mastitis, with fibrous and glandular hyperplasia with retention cysts. The various pathological changes found represented either distinct stages of the disease, or its development according to certain tendencies. Thus, different cases would represent a great variety of processes, and one might find different parts of the same breast showing a variety of pathological changes, almost contradictory in their character. After reviewing the pathology of cyst formation the writer said that it was chiefly with the behavior of the glandular epithelium that they were concerned. It depended on just how far these cells had departed from the normal whether or not transformation into a carcinoma had or had not taken place. Undoubtedly the determining point was the fact that masses of epithelial cells had so infiltrated the surrounding structures that they had penetrated their basement membrane. This corresponded with Adami's definition, "We regard as cancer all cases in which there is infiltrative, and apparently independent, growth of epithelial or gland cells into the surrounding tissues, and this whether of only slightly atypical or markedly atypical cells." The epithelium could go through a very wide range of changes without evincing cancer, but when there was penetration of the cells through their basement membrane, with rupture or loss of basement membrane, this was cancer. In summing up these processes it would be seen that this disease was a very complex one, consisting of chronic inflammation, of hyperplasia of certain of the structures, of the production of fibroepithelial tumors, which were really more than hyperplasias, and finally of the production of cancer. There was no doubt that these various histological changes really represented progressive stages of the disease. The symptoms of this condition were usually tenderness, sometimes pain, in the breast affected; the disease was frequently bilateral. It was characterized by more or less indistinct swelling often amounting to distinct tumor-like masses. The lesions were found principally in the periphery of the breast. There was more a change in texture than a hypertrophy. There was seldom evidence of an active inflammatory process. Retraction of the nipple was not characteristic nor a part of this disease, neither was adhesion of the skin or fixation of the gland to the deeper structures. The progress of the disease was slow and chronic, but it was not steadily progressive. During the earlier stages more or less resolution might take place, but when there had been the production of much hyperplasia restitution to the normal could hardly be conceived. After the menopause complete atrophy might take place. The disease might reach a certain height and remain stationary, or it might undergo transformation into carcinoma. In reply to the question, "Have we any means of determining clinically just what pathological change is present or is taking place!" Dr. Syms said that in a way they had not. There were no reliable statistics to show just what proportion of these cases became cancerous. Finney, quoting other authorities, placed the proportion of cancer at from 10 to 50 per cent. Some clinicians, while vague as to statistics, emphasized the fact that they should be on the lookout for evidences of transformation into cancer, but they failed to tell what these evidences were. Some claimed that one should always regard this condition as being a precancerous state, and that it should always be treated as such, that was by unsparing ablation. Others claimed that one had sufficiently performed his duty if he removed apparent tumor formation. This disease really presented to the surgeon a new problem as he had been seeing these tumors when they were in a full state of development, but the information given the public through the cancer campaign was now bringing these conditions to the notice of the surgeon at an early stage. The surgeon of the future would be seeing a very different type of cases from those that had presented themselves hitherto. A thorough research of the literature showed that there was no unanimity of opinion in regard to the treatment of this condition. The treatment outlined by many was not a logical sequence of their own statements. This condition of chronic cystic mastitis should be regarded as more than a possible cancer; it should be regarded as a precancerous condition, and each case should be considered as a potential cancer. It should be treated as a cancer in embryo, that was by radical ablation of the breast. Simple amputation of the breast was not so effective. The radical operation was no more disfiguring, no more mutilating, no more disabling, and no more dangerous than the lesser and less effective procedure. By pursuing this plan some breasts that might have been preserved would be sacrificed, and an unnecessary major operation would sometimes be performed, but it would result in the greatest ultimate conservatism. If, on the other hand, these patients were watched and the endeavor made to detect signs of cancer formation many mistakes would be made, and if the attempt was made to treat them by partial operation mistakes would be made. In a certain proportion of cases they would remove benign tumors and leave malignant growths behind. If they depended on the microscopic examination of frozen specimens they would be misled in at least a small proportion of cases. This was one of the conditions in which frozen sections should not be relied upon. Early radical operation would result successfully in 100 per cent. of cases; the waiting and watching policy, or treatment by incomplete operation, would result in a certain percentage of failures.

Dr. A. Ernest Gallant said that he had first come to the decision that it was necessary to remove these breasts *in toto* from cases seen at the General Memorial Hospital in 1892. This view had been confirmed later when he heard a paper by Dr. W. W. Keen, in which he showed that every neoplasm, of whatever variety, had in some instances sooner or later degenerated into the malignant type, and he recommended the earliest removal by radical operation of all breasts in which any other than a temporary galactocele was found. Dr. Gallant said that that very day he had seen a nurse whose breast presented the condition so graphically described by Dr. Syms. As the engorgement varied with each menstrual period, and as the periods recurred every three weeks he had advised her to have the metrorrhagia corrected at the source and then be guided by the after effect on the glandular mastitis. The small size of these nodulations could not be taken as a criterion of their benign or malignant nature. Dr. Gallant related the history of a case which seemed to be a simple galactocele which was dissipated by snugly bandaging the breast, but it only made clear the presence of a hickorynut sized tumor. A radical operation was done, but the patient died within twelve months of mediastinal carcinoma. The small nodule proved to be adenocarcinoma. Prompt, radical operation was the only hope of saving these unfortunate women from the danger of malignant disease.

Dr. Forbes Hawkes recalled two cases that had been under the care of Dr. McCosh at the Presbyterian Hospital, in which a cyst had been removed for chronic cystic mastitis and in which there was no suspicion of malignancy; both patients, however, had died within a year and a half of the operation from general carcinomatosis. In cases of so-called chronic cystic mastitis it was better to remove the whole breast by a radical operation for otherwise portions might be left behind containing malignant cells. Many cases of chronic cystic mastitis had enlarged axiliary glands on the same side. He had never had a report of carcinoma on such glands, but thought it was wiser to remove them at the time of the mastectomy.

Dr. Syms, in closing the discussion, said that while one must be convinced of the advisability of a radical operation in these cases, when it came to individuals and became a personal matter the problem was very difficult and one was tempted to do less than his best. Assuming that one in ten of these cases was cancer, then by resorting to the incomplete operation one would be right nine times out of ten, but he would be wrong once in ten cases. This was too great a risk to recommend. There was only one safe advice to give, and that was radical operation. Dr. Syms said that he had

recently been consulted by a young woman about to be married. She had a chronic cystic mastitis with a benign fibroepithelial tumor. Under the circumstances he did not feel like subjecting her to a radical operation. Although Dr. Sendorn had reported that there was no evidence of malignant growth, he would watch the future of that breast with great anxiety and with a great sense of responsibility.

## SECTION ON SURGERY.

*Stated Meeting, Held January 2, 1914.*

DR. CLARENCE A. MCWILLIAMS IN THE CHAIR.

**Case of Syphilitic Splenomegaly.**—Dr. WALTON MARTIN presented this patient with a marked anemia and gummata of the spleen. Cross sections showed two or three little nodules in the spleen, each three or four millimeters in diameter. The spleen was adherent to the diaphragm and when separated there were many places of bleeding. The case was of special interest because of a mistaken diagnosis. Gummata were found all over and through the liver.

**Splenomegaly with Anemia in a Syphilitic Patient.**—Dr. JOHN A. HARTWELL presented this patient, who had lived in the West Indies until 1912. When five years of age he had had a severe dysentery, and when thirteen an illness with fever. He denied any venereal infection. He first began to suffer with slight pain in the splenic region in 1910. It recently had grown severe, and after a severe attack he noticed that his stools would be dark in color and afterward the pain would be relieved. In 1913 he first vomited blood in a large quantity, which necessitated his staying in bed. Examination on admission to the hospital showed anemia and a large spleen, extending seven cm. below the costal margin. The liver was normal in size and there was no evidence of ascites. The blood examination showed red blood corpuscles 1,700,000; hemoglobin 25 per cent.; white blood corpuscles 9,000; polymorphonuclears 75 per cent.; lymphocytes 20 per cent.; large mononuclears 1.5 per cent.; eosinophiles two per cent. Three days after his admission to the hospital they received blood from a man whose blood showed no hemolysis with that of the patient. The patient's spleen increased in size, being eleven and one-half cm. below the costal margin. On April 23, one week after admission to the hospital, the patient received 750 c.c. of the blood referred to. On April 26 there was no marked increase in hemoglobin, but the red blood corpuscles increased to 2,500,000. There were some normoblasts seen. On April 28th the hemoglobin was 20 per cent., and the red blood corpuscles 2,550,000. The patient vomited blood and passed it in the stools in large quantities on April 28 and again on May 9. On May 6 the Wassermann test was strongly positive. Neosalvarsan was administered and also mercuric salicylate and potassium iodide. On June 5th these drugs were discontinued and iron and arsenic were given. The patient continued to improve until July 30th. At various times there were small petechial hemorrhages on the skin and on one occasion in the retina. The patient was readmitted to the hospital on August 15th with a history of having vomited blood and again become weak and pale. The spleen was 9½ cm. below the costal margin. There was liver dulness from the fourth rib to two fingers below the ribs. There was no fluid in the peritoneum. In September the patient developed acute otitis media with pus which healed kindly. On October 3rd there were signs of fluid in the abdomen; on the 6th blood in the stools, and on the 13th the spleen was 15½ cm. below the ribs, and 22 x 21 cm. in extent. The condition of the patient grew worse and on November 18th splenectomy was performed. The spleen weighed 1200 c.c. There was some hemorrhage and a transfusion was done. The patient developed pneumonia and the usual response in leucocytosis. The pathologist reported this to be a case of chronic passive congestion with thickening of the trabeculæ, chronic perisplenitis and large and numerous splenic follicles with fibroid centers. The eosinophile and myoelocytic changes suggested those found in cirrhosis of the liver. Following the operation the patient promptly improved in his blood condition and in two weeks the hemoglobin was 80 per cent. and the red cells were 5,100,000. This case was undoubtedly one of syphilitic cirrhosis with splenomegaly.

**Tuberculosis of the Spleen. Septic Infarction, Polycythemia. Splenectomy.**—Dr. JOHN DOUGLAS and Dr. A. B. EISENBREY presented this communication. They declared that secondary tuberculosis of the spleen was not uncommon, but that true primary tuberculosis of the spleen was probably extremely rare. In cases of so-called primary tuberculosis of the spleen described in the literature, the tuberculous process in the spleen formed the main lesion, the probable original focus of point of entry remaining quiescent or healing, while the process in the spleen developed. The most recent and complete article on this subject was that of Winternitz, who had collected and tabulated fifty-one cases from the literature. Sixteen of these had been operated on with nine recoveries or a percentage of 56. His analysis and summary of these cases were so complete that the conclusions found might be given as follows: "Tuberculosis of the spleen seemed to be equally frequent in the male and female sex. It was most frequent between the ages of twenty and forty, but might occur at any age, the youngest in his list being one year and the oldest eighty years. The symptoms might run an acute or a chronic course; in the acute cases the symptoms were those of an acute systemic infection, while in the chronic cases the onset was characterized by pain or tumor in the splenic region in 70 per cent. of the cases. There might be in addition gastrointestinal or respiratory disturbances. In the list of fifty-one cases the blood count was given in twenty-six. It was normal in nine, or 34.61 per cent., showed anemia in eleven, or 42.30 per cent.; polycythemia in six, or 23.08 per cent. The anemia was not marked in any instance, 3,200,000 being the lowest count. As a rule the leucocytes were not increased, and their number seemed totally independent of the number of red blood cells. Winternitz stated that death always followed if the spleen was not removed. In contrast to this statement they had that of Osler in an article on erythrocythemia who declared that "Splenectomy should never be done in these cases." The list of cases in which the blood picture showed a true polycythemia bore out this latter conclusion. In view of the fact that in their case tuberculosis of the spleen and polycythemia coexisted, these conflicting statements made the question of the treatment of such cases a difficult one. The essayists gave a review of the literature on the subject of polycythemia and reviewed the five theories as to its etiology calling attention to the syndrome first brought into notice by Turk in 1904, namely, enlarged spleen, cyanosis, and high red count. The review of the literature indicated how little really had been definitely determined as to the etiology and essential pathology of polycythemia. The direct relation between polycythemia and tuberculosis of the spleen was open to question.

The case reported was that of a man, 39 years of age, a salesman, whose family history was irrelevant, save that his mother died of nephritis. As a child he had had chills and fever and severe nose bleed. In 1902 he had pneumonia, followed by pleurisy. The previous history of the patient covered seven years. His history taken in 1905 stated that there had been no recent cough, catarrh, or pleurisy, but that during the previous year he had begun to have frequent attacks, during which his face turned purple, and he became very nervous, but he never lost consciousness. In 1907 he complained of momentary attacks of blindness of the right eye from one to six times a day. An oculist reported that his eyes were normal and that the trouble was due to vasomotor disturbance. In 1908 the spleen was palpable one inch below the ribs on deep inspiration. Urinary examination in 1909 showed the presence of albumin, acid reaction, granular and hyaline casts, pus cells, and spermatozoa. The quantity of urine was two quarts in twenty-four hours. Shortly after this he had a severe hemorrhage from the stomach and bowels. He gave a history at this time of cyanosis, flushing, gastric splashing, insomnia, constipation and momentary loss of consciousness. After that he spent a year in the West and made a stay there, from which he returned somewhat improved in health. In November, 1912, he had been suffering from indigestion and pain in the region of the spleen. His chief complaints at this time were severe pain in the left hypochondriac region, radiating toward the midline and across the abdomen, extreme weakness, and a feeling of fullness in the head. His temperature was 101° F. Physical examination of the lungs was negative. There was an indistinct systolic murmur at the apex. The pulse in the right radial was only slightly above normal; in the left radial it was absent. The spleen was palpable about three inches below the free border

of the ribs, and extremely tender. The leucocytes varied between 30,000 and 40,000, and polymorphonuclears were 92 per cent. The condition of the patient remained the same for several days except for a rise in temperature. Believing that he had an abscess or some septic process in the spleen, immediate operation was advised. At operation the spleen was found studded with small white areas which looked like tubercles or miliary abscesses; there was also a large softened area, evidently an infarction. The spleen was only moderately adherent and no tubercles were seen elsewhere in the peritoneum. The liver was apparently normal. After the fourth day the patient appeared to improve for several days, but on the eighth day he became worse; on the ninth day he died. After reviewing the autopsy findings the following anatomical diagnosis was made: Gangrene of the intestines with peritonitis; thrombosis of the aorta, superior mesenteric and common iliac arteries; obstructive arteritis of the celic axis, the superior and inferior mesenteric and left subclavian arteries; tuberculous peritonitis; pulmonary tuberculosis; tuberculosis of the liver; parenchymatous degeneration of the liver and kidneys; acute vegetative endocarditis; theroma of arteries, and hyperplasia of the bone marrow. Smears from the lungs and bronchial glands showed a few tubercle bacilli. Material from the lesion in the apex of the heart inoculated into guinea pigs produced typical tuberculous lesions from which tubercle bacilli were recovered. After reviewing the microscopical findings of the various organs, the essayists stated that a review of the history of this case for the purpose of ascertaining the sequence and possible etiology of lesions gave but little aid. From a clinical standpoint the existence of the marked polycythemia was the most interesting feature of the case. The tuberculous lesion in the spleen would seem to offer a simple explanation for this, and, in fact, attention was called to the enlargement of this organ as early as 1908. The symptoms of flushing and congestion of the face, which continued intermittently throughout and which might or might not have had a possible cause in the polycythemia, began three years before, 1905. Moreover, repeated examinations of the heart and lungs failed to reveal either a circulatory or a pulmonary lesion; nor was there any other evidence of tuberculosis noted. Many of the symptoms referable to the digestive tract were readily explained if it was agreed that the lesions found in the walls of the arteries were of ten years' duration. The lesions themselves offered little suggestion as to their origin, or to any etiological association with the polycythemia. The most obvious cause of death was the gangrene of the digestive tract, which must be attributed to the lesions found in its arterial supply. Obviously there was little possibility of any inferences being drawn as to the results of the operation in cases of tuberculosis of the spleen, or of polycythemia, from their experience in this case. The autopsy findings showed plainly the futility of any therapeutic measures in this particular case. It was of interest to note that for nine days after the operation the red cell count remained high, from 8,000,000 to 7,400,000, while the hemoglobin remained at over 120 per cent. One would expect this result of the "Spleen was the graveyard of the red blood corpuscles" in the adult. The condition of the bone marrow in this and in other cases, and the blood picture after splenectomy, would seem to indicate that whatever its cause the polycythemia, and in this case it was a polycythemia and not an erythrocythemia alone, had its direct pathological factor in the overproduction and over-functionating of the bone marrow. If this presumption was correct the enlargement of the spleen could be explained by an hypertrophy due to an effort to destroy the overproduction of red cells. Finally, if there was a focus of tuberculosis elsewhere in the body from which the tubercle bacilli might enter the blood stream, it would find in the spleen a place of diminished resistance. Thus, rather than as an etiological factor, the tuberculous spleen would be the result of the polycythemia. While they might agree with Winternitz that in cases of tuberculosis of the spleen, when other tuberculous foci were not demonstrable, splenectomy might effect a cure, although their case proved nothing, it afforded some additional weight to the statement of Osler that splenectomy was contraindicated in erythrocythemia.

**A Simple Stitch for Inverting the Appendix Stump.**—Dr. L. MILLER KAHN demonstrated his method of inverting the stump of the appendix which he believed was an improvement over the Dawbarn method.

## SECTION ON MEDICINE.

*Stated Meeting, Held January 20, 1914.*

DR. JOSEPH C. ROPER IN THE CHAIR.

**The Form of the Electrocardiogram; Diagnostic Significance of Its Variations.**—Dr. H. E. B. PARDEE presented this communication. He stated that when the heart muscle contracted electricity was produced by the fibers which were entering into contraction. The direction of the flow of the current depended upon where within the heart the greater amount of electricity was produced. The body tissues conducted this current readily and by putting a galvanometer in the circuit this current might be recorded on a photographic plate. Three leads were used, from right arm to left arm, from right arm to left leg, from left arm to left leg, called lead I, lead II, and lead III. The instrument was connected to the extremities in a constant manner and was standardized so that a movement of one centimeter indicated a current of one millivolt. The direction of the deflection recorded in the leads depended upon the direction of the current within the heart. This direction might be designated by degrees of deviation below having a plus sign, and above having a minus sign, the horizontal with zero degrees lying to the patient's left, and 180° to the patient's right. If the direction within the heart lay between plus 30° and plus 90° then the deflection in each lead would be upward. If the current was opposite to this, that was, between minus 90° and minus 150°, the deflection would be downward in each lead. If the deflection was between plus 30° and minus 30° leads I and II would show an upward deflection; lead III a downward deflection. If the direction was opposite to this, between plus 150° and minus 150°, leads I and II were downward; lead III upward. If the flow was between plus 90° and plus 150° lead I was downward; leads II and III upward, and if the flow was opposite to this, between minus 30° and minus 90°, lead I was upward; leads II and III downward. If the angle of a current approached the border of one of these sectors the value of one of the leads would become very small and would be zero if the angle was exactly on the border. With the angle at the center of the sector the maximum value would be recorded in one of the leads. The amount of the current recorded in the leads, then, depended not only upon the amount produced within the heart, but also upon the direction of the amount to the direction of the line of the lead, and also the value in lead I plus the value in lead III was equal to the value in lead II. The normal electrocardiogram consisted of five waves called P, A, R, S, and T. A certain wave in a certain lead was designated by affixing the numeral of the lead as $P_1$, $P_{II}$. All of these peaks varied greatly within normal limits. The P wave was due to the action of the auricle. It was a rounded elevation with a recorded value of 0.1 to 0.2 millivolts. The angle of its current usually lay between plus 30° and plus 90°, so that it was directed upward in all three leads. Hypertrophy of the auricle resulted in an increase in the maximum value of P. A premature auricular contraction resulted in a P wave of abnormal form. The wave was absent in auricular fibrillation, being replaced by a series of small undulations in the line of the record, best seen in lead III, and considered to be due to the muscle bundles of the auricle contracting incoordinately. Between P and Q was an interval during which the record remained at zero. During this time the impulse was passing along the bundle of His and had not yet caused the ventricles to contract. The interval from the beginning of P to the Q wave was usually about 0.18 of a second, not over 0.2 of a second unless some degree of heart block was present. The waves Q, R, and S were due to the rapidly changing currents at the beginning of ventricular systole. Their combined duration was not over 0.08 to 0.09 seconds, and if greater than this indicated myocardial impairment. R represented the direction of the predominant current of this period. Its angle lay between plus 30° and plus 90°, so that $R_I$, $R_{II}$, $R_{III}$ were upward. $R_{II}$ was the largest and varied from 1.0 to 2.0 millivolts. The direction of the current producing R changed with cardiac hypertrophy. If left ventricle hypertrophy predominated the angle was deviated toward the left and lay above plus 30° so that $R_{III}$ was downward. In extreme cases it might lie above minus 30° so that $R_{II}$ was downward also. When hypertrophy of the right ventricle predominated the angle was deviated to the right and lay above plus 90°

so that $R_I$ was downward. In marked cases $R_{III}$ might also be downward. When the heart was dilated there was no change in the angle of R, but the weakness of the contraction resulted in R having a small maximum value. In strongly contracting hearts this value was large. At the end of S the whole ventricular mass was contracting so that the potentials neutralized each other and the record stayed at zero. The T wave followed, was usually upward in all leads, and had a maximum value in hearts with poor myocardium. Premature ventricular contractions resulted in a characteristic complex. First a very large deflection remaining away from the base line for 0.1 of a second or more and then a swollen deflection usually in the opposite direction, and, though larger, bearing a resemblance to a T wave. This unusual form was due to an abnormal course of the contraction through the ventricles. If the contraction originated in the right ventricle, the first limit was upward in lead III; if in the left ventricle, it was downward in lead III. Displacement of the heart affected the angle of the peaks and therefore the form of the electrocardiogram. The expiratory movement of the diaphragm, as also abdominal distension by gas or fluid, would displace the apex upward. The base was held by the blood vessels and could not follow so that the point was rotated upon the basal region at a fixed point. This changed the angle of the waves and all the waves were changed in the same direction. Respiration appeared as a rhythmical waxing and waning of the peaks and in the normal electrocardiogram they increased in lead III on inspiration and decreased on expiration. In lead I the behavior was opposite. Lateral displacement of the heart, as by air or fluid in the pleura, fibrosis of the lung, or tumor, carried the base with the apex so the heart was not rotated and the angle of the peaks was unchanged. Thus a normal angle of the R wave, if the area of dullness was changed, spoke against hypertrophy and for displacement or dilatation as possible causes.

Dr. Horatio B. Williams called attention to the fact that although there were many things not known in regard to the electrocardiogram it was a significant fact that its study gave them considerable aid; because a certain part of the curve was not known did not necessarily mean that the method did not possess great utility and importance. Clinicians observed complicated phenomena which were unknown to them, yet the observation of the same was of importance. By the observation and groupings of certain facts they were able to arrive at conclusions. To say in an empirical way that it was impossible to attach any clinical significance to the variations in the curve, even though one could not know precisely what their physiological significance was in every case, would be a mistake. One of the important clinical facts was that in the same person, provided the heart was not diseased, the form of curve was constant. The method of attaching the instrument should be studied carefully if the record was to come out the same. This differed from taking the pulse rate. It should be remembered that even the skilled operator was not always the same on different days. Changes in the heart itself were shown in the electrocardiams which were not often misleading. They might have a precise knowledge of their clinical significance, and again they might not. Hitherto certain changes had been grouped together. In an irregular heart some located the irregularities as starting in the auricles, others in the ventricles. In the course of years he hoped they would be able to determine which irregularities were innocent and which not. The conclusion must be that the use of the electrocardiograms was quite justifiable.

Dr. Neuhof reported the case of a girl, sixteen years of age, who presented clinically very marked left ventricular hypertrophy but who did not show the electrocardiogram of this condition. The orthodiascopic tracing showed that the heart was also considerably enlarged to the right; this counterbalancing enlargement may have accounted for the absence of electrocardiographic evidence of left ventricular hypertrophy. He also reported the case of a woman, 26 years of age, whose heart was absolutely normal, yet the electrocardiogram showed the complex of right ventricular hypertrophy. By orthodiascopy the heart was found lying flatter than normal, an example of the "flabby heart" of Waller. This apparently accounted for the rotation of the ventricular axis from the normal, the first thus becoming the "strong" lead. These cases alone show that other factors besides hypertrophies had to be considered as causes of the complexes of ventricular hypertrophy, and that clinical and particularly orthodiascopic examinations were very important in the study of these complexes.

Dr. H. E. B. Pardee, in closing the discussion, said they could not take the electrocardiogram alone any more than they could any other one method of examining the heart. This fact was mentioned under respiratory variations. In one case of aortic insufficiency the electrocardiogram showed the picture of a right hypertrophy; why it showed that he did not know, but he expected as our knowledge progressed we would be able to understand these apparent paradoxes.

**Some of the Psychic Mechanisms in the Organic Amnesias.**—Dr. S. P. Goodhart presented this communication. He stated that the relationship between certain of the psychic manifestations, hitherto regarded as purely functional, and symptoms of organic origin was becoming more apparent. The domain of psychology offered opportunities for limitless observation of what appeared to be purely functional symptoms on the one hand, and organic symptoms on the other. A study of the amnesias opened this relationship to view. Memory might be considered as primarily a simple organic process, developing later higher biological features. In its developed form as we know it, especially in its relation to ego-consciousness, it was really something superadded to the organic memory. There was no one center in the brain that could be regarded as the memory center; in other words, memory was brought about by combinations of visual, auditory, tactile and motor images. Much of the so-called organic memory became relegated to the subconscious. During the past few years the essayist said he had observed a number of cases of amnesia in neuropathic individuals in whom the etiology indirectly was nicotine, or the toxin of malaria, or, as in one very interesting case, of traumatic origin. In all of these cases there was one psychological mechanism which formed the direct exciting factor and that was repression, the desire to eliminate and to stamp out from consciousness a part or the whole of the past, a forcing into the subconscious of unpleasant experiences. In all of these cases there was strong internal emotional conflict. The case of Professor X represented the influence of the psychic factor in the toxic amnesias. This patient was fifty years of age and had a good family and personal history. Though highly intellectual and cultured he was of the neurotic type, and since boyhood had used tobacco excessively as a solace to depressing experiences and mental strain of a personal character. The amnesia came on suddenly, shortly after indulgence in the usual allowance of tobacco in addition to a quantity of strong coffee. The patient became suddenly dazed, and although fully conscious lost entire recognition of environment and personality. While the ego-consciousness was preserved, cognitive memory was lost. This condition continued for three weeks when complete re-establishment of the mental association took place more or less suddenly. The three weeks of lost memories were obliterated as a unit from the patient's life and there still remained, after seven years, only a vague recollection of the experience. Nutrition, absolute rest and withdrawal of all tobacco were the only remedies. Periodic excesses in tobacco were even now followed by slight amnesic seizures and intense paroxysms of hemicrania. In this case he had not deemed it wise to restore the dissociated conscious fragments of memory to the control of the upper consciousness. Wisdom might dictate this, for the reason that psychanalysis had taught them that it was as a rule best to place these emotional experiences within the grasp and recognition of the ego-consciousness. The element of repression was an intense emotional upheaval preceding the amnesia, and on the day of its sudden appearance and shortly before there had occurred a psychic trauma, which the patient would naturally and did try to suppress. Dr. Goodhart then related the history of a teacher, twenty-seven years of age, who lost memory as to personality and environment after intense emotional strain in whom the exciting factor was the malarial toxin. The dissociation covered events and experiences of the immediate past and part of the preceding Summer. This patient fully realized her condition and it perplexed her. The writer referred to an interesting case reported by Grey and Emerson in a recent number of the *Journal of the American Medical Association*, in which apparently lost visualizing power stored away in the subconscious was restored in the course of a few hours after the removal

of a small cerebral tumor from the right parietal region. From a study of this case it was evident that she last the power of visualizing images after a skull injury sustained at the age of eight or ten years. The interesting psychological study of the waking and dream states, in this case, strikingly suggested the repressive element, probably suddenly induced by the original cranial injury, and as suddenly relieved by the removal of the small tumor. It seemed hardly possible that both occipital lobes, the seat of visual cortical representation, should have been affected by this small growth, especially as it was evident that the amnesia dated from the cranial trauma and thus before the probable development of the tumor, and yet removal of the tumor instantaneously brought about reappearance of memory. Another case cited illustrated the value of psychanalysis, though the psychic state of phobia and physical manifestations were apparently the result of tobacco intoxication. These methods developed the origin of his phobias and some obsessions as being of a sexual character, though the writer said that he did not believe with Freud that they invariably were. The attempt to submerge the memory of the past in complete oblivion was brought out thoroughly by the case of a young clergyman, a man of culture and education, who suffered a severe head injury as the result of a fall. Recovering consciousness at the end of two hours, though there was no evidence of external injury, his memory for the entire past, including knowledge of his environment and his personal identity, was gone absolutely. There was no objective evidence of lesion to the nervous system. The loss of memory was so complete in this case as to include even the elementary knowledge of the simple functions of the body; that was he could not interpret hunger, did not know how to walk, etc. Time relationships were likewise lost. There was a complete splitting off of the entire past from conscious life. After six weeks of re-education the knowledge at his conscious disposal represented the acquired experiences of the time from the date of the accident. By the study of his dreams and other psychological methods they were able to show the presence of past memories hidden in the subconscious. By applied psychological methods they were able to stimulate the mass of experiences representing the sleeping self into activity. This personality represented the life experience up to the time of the accident and was an entirely different individual. The two personalities finally alternated, leaving the man in that condition known as dual personality. In their endeavor therapeutically to stimulate the two personalities by psychological methods, the patient cooperated, but at the cost of intense emotional conflict. It was as though the one personality were trying to suppress the other. The one personality was that of the man before the accident, being an individual of esthetic tastes, intense spiritual feelings, and firm religious belief. The second personality was entirely different, seemingly having none of the religious feeling and being more worldly. The case represented a true dissociation of consciousness, a complete amnesia. Its direct etiology was traumatism. The true psychological element was internal conflict, the result of an effort at suppression. There could have been no localized lesion to have caused such an amnesia. The past memories really were present, though lost for the time being to the upper consciousness. The fact was that this young man wished to suppress the past in some details vital to his life. It developed that he wished to throw off the shackles that held him to his profession as a clergyman. There were other emotional experiences that were likewise repressed, as was developed in the course of their psychological investigation. The limitations of the clerical life were contrary to his inherent philosophical and analytical mind. There was necessarily a conflict. The stronger personality in this case was that dating its re-education from the time of the fall. Thus it was seen how much easier it was for the new personality to assert itself. What was known as the intermediary state in these cases, that representing the transformation from one personality to the other, was really identical with the psychic and physical state at the time of the trauma which split the consciousness. This final intermediary state was attended with great physical prostration, a very slow pulse, and almost complete anesthesia for all forms of sensation, while the psychic state was undergoing the conflict of the two personalities. There was no doubt that had they not stimulated the hidden memories of the primary personality the person would have remained in the secondary state. Further studies along these lines would doubtless enable them to see much closer relationships betwen psychic symptoms and organic causes. There was a border line land in which lay hidden lines of cleavage in consciousness which might be completely disassociated by organic processes.

**Remarks upon Mental Infantilism in the Tic Neurosis.**—Dr. L. PIERCE CLARK read this paper. (See p. 553.)

Dr. FOSTER KENNEDY said that the pendulum had swung as regarded the attitude of the neurologist toward spasm, particularly the tics. It was not long since torticollis was operated upon because the condition was looked upon as of organic nature. This condition was in a genesis absolutely psychological. Dr. Clark had shown the psychological mechanism, and accounted for the swing of the pendulum from the organic viewpoint. Some of them looked upon the tics as purely neurological. Dr. Kennedy thought this was going further than the facts would warrant. In regard to the last case spoken of by Dr. Clark, might not the dipsomania of the mother have been a contributing factor? And, further, might not the offspring of an alcoholic mother provide a good soil for the tic? There must have been some determining factor not yet spoken of which when thrown off permitted the patient to become a normal steady man. Some further investigation should be carried on to find the difference in the psychopathic personalities and the normal individual from a precise analysis of the mechanism itself.

Dr. A. A. BRILL said he was much interested in Dr. Clark's paper. He considered tics and mental torticolles as psychoneurotic manifestations and always found them as symptoms of some particular neurosis. The treatment which he found to be most efficacious after he had tried all other recommended treatments was psychanalysis. Some of these patients were psychopathic individuals from the beginning and were therefore difficult to cure. Some got well and some did not. Dr. Brill said he agreed with Dr. Kennedy that there may be something physical at the bases of these neuroses, but as it had not been found yet, and as physiotherapy was of no avail, it was only reasonable that they should be treated by psychotherapy. The possibility of a physical basis was also thought of by Freud, who stated that in more than half of the severe cases of psychoneuroses he positively succeeded in demonstrating syphilis in their fathers before marriage. The patients themselves showed absolutely no sign of hereditary lues, so that the abnormal sexual constitution was to be considered as the last offshoot of the luetic heredity. In his own cases Dr. Brill did not find that heredity played any definite part. That was whenever the patient was mentally normal—all other things being favorable—a cure could always be effected by psychanalysis irrespective of hereditary taints. As to infantilism, all such patients show in their symptoms infantile components. By a process of regression the symptoms were either direct or negative infantile manifestations. Dr. Brill found very few ticuers among homosexuals.

Dr. LOUIS CASAMAJOR said he was most interested in the etiology. If one went back and read over some of the textbooks he would find tabes and paralyses written with the etiological factors of alcohol and tobacco, wet, cold, and trauma. Tabetic trauma played a minor part in the formation of these amnesias. They should get away from their stereotyped ideas regarding the etiology. If these others were taken away they would only have syphilis to fall back on. These things represented an obscure element, forgotten unpleasant incidents. If an individual could forget some unpleasant incident, forget some large section of his life, and get interested in something, you might cure him. He recalled the case of a young man who was absolutely amnesic after a tumble. There was a period of unconsciousness and then amnesia. In studying the case and the elements which led up to the amnesia a plan was formed which resulted in his recovery. The point of the matter was that the man was found to be mixed up in crooked politics and so forth and was in danger of a jail sentence because of the misappropriation of funds. The interesting point centered in the personality of the man. He asked what became of the man Dr. Goodhart reported. Was there a mean between two personalities? The study of the character of these individuals was interesting. These people did not do things well. They were neurotics and were looked upon as fools. After an analysis they did not seem to be the sort of fool thought at first. He believed the swing of the pendulum was going too far and it might be better to consider operations upon patients with torticollis. He re-

called one patient who was cured by a section of the spinal accessory nerve on the wrong side.

Dr. L. PIERCE CLARK, closing the discussion, believed that the point was well taken and that undoubtedly individuals were predisposed. Many of them had an unusual susceptibility and were highly emotional in the early stages. Dr. Clark believed that in time these cases would be based as temperamental. They all found them temperamental and not purely physical.

### THE PATHOLOGICAL SOCIETY OF PHILADELPHIA.

AT a stated meeting held February 12 Dr. ALFRED STENGEL exhibited a specimen of "Hydatid Cyst of the Liver." The patient was a Russian Hebrew who had come to the United States from Northeastern Germany, and who presented a tumor in the right hypochondrium, for the relief of which operation was performed and the surgeon, discovering globular masses in the liver that he took for malignant disease, closed the wound without removing the diseased tissue. The symptoms continuing and a leucocytosis being present operation was undertaken a second time at a later date, when fluid was evacuated and drainage provided for. Through the opening thus left grape-like masses made their escape, and these on examination were found to contain scolices and hooklets characteristic of cysticercus cellulosæ. Under a persistence of the treatment the discharge ceased in the course of a short time and eventually the wound closed, leaving the patient quite well.

Drs. JOHN A. KOLMER and ROBERT S. MCCOMBS presented a specimen of "Sarcoma of the Esophagus" and one of "Carcinoma of the Esophagus." With respect to the former it could not be determined definitely whether it had arisen as a primary growth in the esophagus or had extended to this tube from mediastinal glands involved in the disease. Metastasis had taken place to the liver and other organs, and rupture had occurred into the posterior mediastinum. In connection with the second specimen perforation had taken place into the left primary bronchus, and of this communication the patient was conscious, food ingested in the ordinary way being returned by vomiting. Death resulted from aspiration pneumonia.

Drs. JOHN H. JOPSON and JOHN A. KOLMER presented a specimen of "Carotid Tumor." The growth was removed from the neck of a patient on the supposition that it was a tuberculous gland. It was found attached to the external carotid artery, which had to be ligated to permit of the removal of the mass, and on histologic study it was found to present the appearances of an endothelioma.

Dr. M. B. HARTZELL presented a specimen of "Colloid Degeneration of the Skin."

Dr. ROBERT N. WILLSON, JR., presented the heart, kidneys, and brain from a case of uremia. The patient was a man with Cheyne-Stokes breathing, high blood-pressure, signs of arteriosclerosis and albumin, and tube-casts in the urine. The patient denied syphilitic infection, and the Wassermann reaction was negative. After death the heart was found to be enormously enlarged, but without valvular lesion, and all of the cavities, with the exception of the left auricle, contained masses of chicken-fat clot adherent to their respective walls. The descending thoracic and the abdominal aorta was the seat of extreme atheromatous ulceration, and the cerebral vessels were stiff and patulous. The kidneys were small, although the capsules stripped readily, and there was little change in the relations between cortex and medulla. One kidney contained a moderate-sized cyst.

Dr. A. H. HOPKINS presented a communication entitled "Preliminary Report on the Determination of Blood-sugar by the Micro-method of Bang." The method was found entirely reliable, its great advantage consisting in the small amount of blood, only three drops required.

Dr. HERBERT FOX read a paper entitled "Pathology of the Thyroid Gland in Wild Animals." He reported the results of observations made on animals dying at the Philadelphia Zoological Gardens over a period of ten years and he described the various forms of thyroid disease encountered.

Drs. JAY F. SCHAMBERG and JOHN A. KOLMER presented a communication entitled "A Study of the Germicidal Action of Chrysarobin and Other Drugs Used in the Treatment of Psoriasis." The tests were made with the *Staphylococcus epidermidis albus* as the organism most commonly found in the skin in connection with the lesions of the disease. In addition to chrysarobin, pyrogallic acid and preparations of arsenic and also calomel were studied. Of all of these only the last exhibited any germicidal influence.

## Books Received.

*The* MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DIAGNOSEN AV BARNETUBERKULOSENS KLINISKE INITIALFORMER. HERMAN G. GADE. Paper; illustrated; 112 pages. Steen'ske Bogtrykkeri, Kristiania.

DIE HOMOSEXUALITÄT DES MANNES UND DES WEIBES. By Dr. Med. MAGNUS HIRSCHFELD. Paper; 1067 pages; price 12 marks. Louis Marcus, Berlin.

STUDIES FROM THE DEPARTMENT OF PATHOLOGY OF THE COLLEGE OF PHYSICIANS AND SURGEONS, Columbia University, N. Y. Vol. XIII, 1913. Reprints. Paper; illustrated; 501 pages.

THE UNEXPURGATED CASE AGAINST WOMAN SUFFRAGE. By Sir ALMROTH E. WRIGHT, M.D., F.R.S. Price $1 net; cloth; 188 pages. Paul B. Hoeber, New York.

GEBURTENRÜCKGANG UND MÄNNLICHE SEXUAL IMPOTENZ. By Dr. P. LISSMANN. Paper; price 1.50 marks; 37 pages. Curt Kabitzsch, Wurzburg.

THE BIOLOGY OF THE BLOOD-CELLS. By O. C. GRUNER, M.D. Cloth; price $6 net; 392 pages. William Wood & Co., New York.

MORTALITY STATISTICS, 1912—Thirteenth Annual Report. Department of Commerce, Bureau of the Census. Wm. J. Harris, Director. Prepared under the supervision of CRESSY L. WILEUR, M.D. Cloth; 382 pages. Government Printing Office, Washington.

## Therapeutic Hints.

**A Prescription for Gastric Hyperacidity.**—W. Wolff recommends the following combination:

℞ Extract of belladonna, 0.2 gram.
Bismuth carbonate,
Calcined magnesia, of each, 7.5 grams.
Sodium citrate, 15 grams.

Of this powder the tip of a knife bladeful is to be taken every three hours, between meals.—"Taschenbuch der Magen und Darmkrankheiten."

**Liquor Ammonii Anisatus.**—This preparation of the German Pharmacopœia, as well as of most of the other pharmacopœias of Europe, is not as well known among American physicians as it should be. It is a valuable expectorant, consisting of 1 part of anise oil, 5 parts of ammonia water, and 24 parts of alcohol. The dose is 0.25 to 0.75 gram or 5 to 15 drops three times daily. It is usually given in mixtures with other expectorants, as follows:

℞ Infusion of ipecac root, 150 grams.
Ammonium chloride, 5 grams.
Liquor ammonii anisatus, 5 grams.
Syrup of senega, 25 grams.

The dose is 1 tablespoonful. This mixture may be prescribed for patients suffering from bronchitis, who give evidence of prostration and who are not running a temperature.

℞ Liquor ammonii anisatus, 1 gram.
Infusion of senega root, 100 grams.
Syrup of fennel, 25 grams.

The dose is one-half teaspoonful every hour, as an expectorant following acute bronchitis in children.

℞ Liquor ammonii anisatus, 5 grams.
Bitter almond water, 10 grams.
Orange flower water, 50 grams.

The dose is 1 teaspoonful to be taken 2 or 3 times a day in a teacupful of a demulcent drink, such as slippery-elm tea.

An old preparation known as "Liquor pectoralis" has the following formula:

℞ Liquor ammonii anisatus, 5 grams.
Syrup of althea, 30 grams.
Distilled water, ad 200 grams.

The dose for an adult is 1 teaspoonful three times daily.

**Gelatin as a Hemostatic.**—The action of gelatin in favoring the coagulation of the blood has long been known. It has been employed subcutaneously and intravenously in internal hemorrhage, in hemophilia, in purpura, in the hemoptyses of tuberculosis, and in the various hematemeses. The best results have been obtained apparently in the treatment of aneurysm, chiefly of the aorta. The formula for the "gelatinized serum" is as follows:

℞ Sterile gelatin, 10 grams.
Sodium chloride, 7 grams.
Distilled water, 1,000 c.c.

The solution should not be acid. The possible presence of the spores of tetanus in commercial gelatin demands rigid sterilization. The gelatinized serum should be kept at 110° C. for at least a half-hour. It may be administered in doses of from 20 to 200 c.c. per day. The liquid should be injected at 37° C. into the subcutaneous tissue of the thigh or abdomen. The intravenous route is rarely employed. Gelatin has been injected directly into the cavities of aneurysms, in some instances with good results.

### A METHOD FOR PLICATING VOLUMINOUS CECA.*

By JOSEPH A. BLAKE, M.D.,

AND

JAMES N. WORCESTER, M.D.,

NEW YORK.

Two years ago I described this operation before the New York Surgical Society and exhibited a patient, upon whom I had used it.†

At that time several patients had been operated upon but the time elapsed from their operations had been so short, only two months in the earliest case, that no deductions could be made as to the results obtained from the operation.

Since that time quite a large number of patients have been operated upon by my colleagues and myself without any deleterious effect upon them and apparently with sufficient betterment of their symptoms to warrant the belief that the operation is of enough value to again call attention to it.

The condition for which the operation was devised presents a well-defined symptom complex in which the major symptom is pain in the right lower quadrant, occurring in ill-defined attacks and associated with gas. There is also, as a rule, constipation, and in many cases general evidences of intestinal autointoxication. There may be a more or less well-developed colitis. Upon examination of one of these patients one finds evidences of distention of the cecum, marked by tympany and splashing, and usually, the balloon-like cecum may be felt or even seen. Radiography with the aid of bismuth, shows the cecum to be large both in diameter and in length, to often hang into or lie in the true pelvis, and also that it fails to empty itself in the normal period.

Upon operation the cecum is found to have a more or less free mesentery and to be more than usually movable, hence the term cecum mobile, which is usually used to describe the condition.

It is my conviction, however, that it is not the mobility of the cecum but rather its lack of tone and its dilatation that are the causes of the symptoms. The importance of this question is at once manifest. For, on the one hand, if the symptoms are to be explained by too much mobility, fixation would be the better treatment; on the other hand, if they are due to atony and dilatation any method of fixation, which necessarily must embarrass the contractility of the intestine, is contraindicated and an operation enabling the intestine to empty itself more efficiently should be sought for. Apparently, surgeons are becoming convinced that mobility of the intestine does not interfere with its motility and contractility; and operations for the fixation of the cecum are becoming less popular. However, there is a marked tendency to attribute overdistention of the cecum and stasis there and in the lower ileum to peritoneal folds producing constrictions and kinks; and we are hearing continually of Jackson's membrane and Lane's kinks. As has been well shown Jackson's membrane is a normal structure, present in nearly all individuals although undoubtedly more marked in some, and it has yet to be demonstrated that compression by it or kinking of the ileum by the variable peritoneal folds of the ileocecal region are sufficient to cause obstructive symptoms. One who has observed the hypertrophy of the muscularis that occurs in long-continued obstructions of the intestine cannot reconcile the thin atonic muscularis of the voluminous cecum with the theory that it is dilated because of obstruction.

In 1905 I described a condition productive of many of the symptoms we are considering, in which the end of the cecum was suspended as it were by the mesoappendix in some cases in which that organ passed upward and inward behind the ileum or ileocolic junction. Removal of the appendix in these cases freed the cecum and the pain was relieved. The possibility of kinking of the ileum over the mesoappendix was mentioned also.*

What the cause of the voluminous atonic cecum is is not altogether clear, but it would seem to be due to several factors acting together. I think I am correct in stating that intestinal autointoxication is very rarely observed in people who have short, large intestines; while it is relatively common in people in whom particularly the first part of the large intestine is long and voluminous.

While it seems most probable that the size of the cecum and colon is dependent upon congenital influences, undoubtedly stasis is a more or less acquired condition. Nearly all patients suffering from stasis have a weak and atonic musculature, both skeletal and intestinal. If the muscular tone is increased and the abdominal muscles strengthened so that they afford real active contractile support, and even a sort of massage to the intestines, instead of the abdominal wall being simply a bag, intestinal stasis can hardly exist. Even if one fills the abdominal cavity with that inert and incommoding substance fat, the patients are improved. Intraabdominal pressure, in other words, is most necessary. Support must be afforded to the large abdominal veins, otherwise the portal circulation is slow and the intestinal muscularis becomes atonic.

While myasthenia is a cause of intestinal stasis,

* Read at the 260th meeting of the Practitioners' Society Feb. 6, 1914.

† A New Method for Operating upon Voluminous Ceca or Cecum Mobile. *Annals of Surgery*, Vol. LV, p. 767, 1912.

*"Annals of Surgery," Vol. XLII, page 394, 1905.

it is none the less a result, and these wretched patients become the victims of a vicious circle, to which is often added neurasthenia with its hyperesthesias of the abdominal type.

Unfortunately most abdominal operations weaken

FIG. 1.—Introduction of first stitch of suture and method of tying first knot, after inversion of stump of appendix with pursestring.
FIG. 2. Entire suture introduced; in practice each stitch is drawn tight before introducing the next.
FIG. 3. Suture introduced, drawn tight, and tied, thus diminishing the length as well as the diameter of the intestine.

the abdominal wall and it becomes relaxed, particularly if the patient cannot exercise the abdominal muscles for fear of producing hernia. Belts and supports only help passively in maintaining intra-abdominal pressure, and should never be used when a good abdominal musculature can be obtained by proper exercise.

In considering the treatment of stasis we must not lose sight of the fact that it is the normal function of the cecum; for it is evident from comparative studies that the cecum is designed to be a macerating chamber. We cannot control this function except by hurrying things through it, diminishing its capacity, or doing away with it altogether. On the other hand we can obviate some of the bad effects of stasis and absorption if we put things into it that do not in undergoing decomposition form hurtful products. But as the stimulation of peristalsis is largely dependent upon the bulk of the intestinal contents a large amount is necessary to provoke activity in a large cecum. If the cecum is proportionately larger than the rest of the intestinal tract, manifestly stasis will occur unless a larger amount of food is ingested than the rest of the intestine can take care of, and, therefore it is imperfectly digested and harmful fermentation and decomposition take place.

I have made this excursion into the causes and effects of intestinal stasis in order to explain the *raison d'être* of the operation I am about to describe.

An operation for overcoming intestinal stasis must either be so radical and so certain, in itself, of giving relief, as to negative its effect upon the system of the patient and particularly the risk, inherent to large incisions, of weakening the abdominal walls; or it may be designed to simply aid the patient by breaking one of the links in the chain, thus enabling him to overcome the rest. Manifestly such an operation must be slight and must not jeopardize the integrity of the abdominal walls.

The only operation that promises complete relief from intestinal stasis is excision of the cecum, the ascending and part of transverse colon. In a paper read before the American Surgical Association in 1910* I advocated this, but questioned its advisability except in the very worst cases that had resisted every other method of treatment. In fact I have only advised it in two patients and neither of them have consented, probably because my statement of its benefits were none too sanguine. I still believe, however, from the good results I have obtained when excising this portion of the colon for carcinoma, that it would in all probability give relief. If done, the ileum should be implanted into the remnant of the transverse colon and not into the sigmoid flexure; because the functional result is better from the former method.

The operation, the results of which I am about to report, was devised as a merely palliative one and only to be done when the abdomen had been opened for another purpose. In other words its results were too problematical to warrant its performance for the treatment of stasis alone.

It has been nearly always done during an operation for appendicitis when from the symptoms and the appearance of the colon it was judged that there was too much stasis and retardation in the cecum and ascending colon.

The operation is a very simple one as can be seen by reference to the figures (Figs. 1, 2 and 3), and consists simply in stitching the ventral and

FIG. 4.—Before operation; large cecum hanging over the brim of the pelvis.

lateral teniæ together after the appendix has been removed; thus folding in or plicating the cecum and ascending colon. A non-absorbable suture of silk or linen is used, and the stitches

*Surgery, Gynecology, and Obstetrics*, July, 1910.

are taken a long way apart, usually about two centimeters or a little less, so that when the stitch is drawn tight the length as well as the diameter of the gut is diminished. The stitching is carried aborally as far as is practicable, usually for ten to fifteen centimeters. The contractility of the gut is not impaired as it would be if part of the wall were excised, and it is believed that on account of its diminished capacity there is not so great a tendency to accumulation and stasis. Apparently the results confirm the reasonableness of this belief. The procedure only adds three or four minutes to the length of an operation, and, so far, apparently, has not influenced the postoperative recovery.

Since the plication has only been done in the course of an operation for appendicitis or some other condition it has not been always clear how much benefit has accrued from the plication itself, yet in the majority of the patients improvement in certain symptoms has resulted which could hardly be explained in any other way.

Fourteen patients have been followed from one to a little over two years; the first plication having been done in November, 1911.

Subsequent radiographs to show the size and position of the cecum have been taken in only one patient. Those taken three months after operation showed the cecum to be much smaller and higher up than before operation. (Figs. 4, 5 and 6.)

The morbid condition present, as shown by the pathological reports, were chronic appendicitis in ten, subacute appendicitis in one, and acute appendicitis in one. One patient had an umbilical hernia and a normal appendix. In one the appendix was not examined but was probably nearly nor-

Fig. 5.—Immediately after operation; bismuth scarcely enters the cecum.

mal. Three patients had cystic ovaries, two had lacerations of the cervix and one had retroversion of the uterus. Reports were obtained from these patients upon their symptoms which were classified for comparison into *pain, constipation, gas* and *intestinal distention, gastric symptoms* and *intestinal autointoxication.*

*Pain.*—All the patients with one exception had suffered pain. It was entirely cured in six (46 per cent.), much improved in one, and improved in five

Fig. 6.—Three months after operation; the cecum has regained some of its caliber, but is still short.

(38 per cent.). One patient was unimproved (8 per cent.).

*Constipation.*—No note was made as to constipation in one patient and it was not complained of by three. Of the remaining ten it was obstinate in three, marked in five, and moderate in two; seven (70 per cent.), were permanently improved, one was temporarily improved, and in two (20 per cent.) there was no improvement.

*Gas and Intestinal Distention.*—Were not noted in two. They were marked in nine patients and only moderately complained of by three. Of these twelve, one (8.5 per cent.) was entirely cured; eight (66 per cent.) were improved, one (8.5 per cent.) was temporarily improved, and two (17 per cent.) were not improved.

*Gastric Symptoms.*—Seven patients complained of marked gastric symptoms. These were improved in five (71 per cent.) and unimproved in two (28 per cent.).

*Intestinal Autointoxication.*—Six patients suffered from marked symptoms of autointoxication. Of these five were improved and one unimproved.

Eleven patients expressed themselves as generally much improved; one as improved for six months when she developed uterine fibroids, for which she has since been operated.

Two patients were not improved as to their general health: One of these apparently was at the commencement of a nervous breakdown at the time of operation and now has nervous prostration. One patient attributed most of her benefit to the after treatment.

It is difficult to draw definite conclusions from a stilted report of symptoms, but both Dr. Worcester and myself have been impressed that these

patients received more benefit than they would have without the plication. Manifestly it cannot be considered a curative measure worthy of being performed by itself, but it appears to be well worth doing in the course of an operation for something else when the symptoms call for it.

## DRAINAGE OF THE BLADDER FOLLOWING SUPRAPUBIC OPERATIONS.

BY CHARLES H. CHETWOOD, M.D., LL.D.,

NEW YORK.

PROFESSOR OF GENITOURINARY SURGERY, NEW YORK POLYCLINIC; VISITING SURGEON TO BELLEVUE HOSPITAL.

Most of us well appreciate the great importance of efficient vesical drainage in connection with the high operation, on account of the faulty mechanical conditions that necessarily attend this procedure, which are more especially objectionable when the bladder is the site of an old chronic lesion, accompanied by decomposing urine and inflammatory products. The excellent opportunity of approaching the bladder afforded by this method, however, has given an impetus to the development of a proper means of drainage thereafter, which seems to have been productive of only a moderate success. Among different expedients tried have been the trap and syphon, used primarily by dentists, and a tip cup contrivance, that is regulated to overflow at required intervals and provide intermittent syphonage.

I especially recognized the value of the successful accomplishment of good bladder drainage attending a suprapubic operation, this past winter, for the removal of an enlarged prostate and vesical stones in a patient who weighed over 300 pounds, and whose abdominal wall was lined with a fatty layer of 3 or 4 inches' thickness. The result in this case was satisfactory beyond expectation. There was no fat necrosis, which so often occurs in such cases; there was no sloughing of purulent membrane during repair, and the bladder wound was practically healed three weeks after operation, the patient having been kept continuously dry for the entire period that is otherwise usually so uncomfortable. This was attained, not by the ordinary method, but by the adaptation of the laboratory hydraulic pump, as has been utilized in operative procedures upon other parts of the body, and consists of a metallic hydraulic suction pump, attached to a convenient water tap, an aspirating bottle, and a fenestrated tube, with a small interior cannula, for introduction in the wound or cavity to be aspirated (Fig. 1). For the bladder, a somewhat different arrangement is required at the wound. In the beginning a large drainage tube is inserted in the bladder, in the interior of which is a smaller rectangular hard-rubber or glass suction tube. The water is at first allowed to run continuously, so as to keep up the suction, and as the wound heals and retention within the bladder commences, the nurse is instructed to start the suction apparatus at stated intervals, to be determined by the rapidity with which the accumulation of urine occurs.

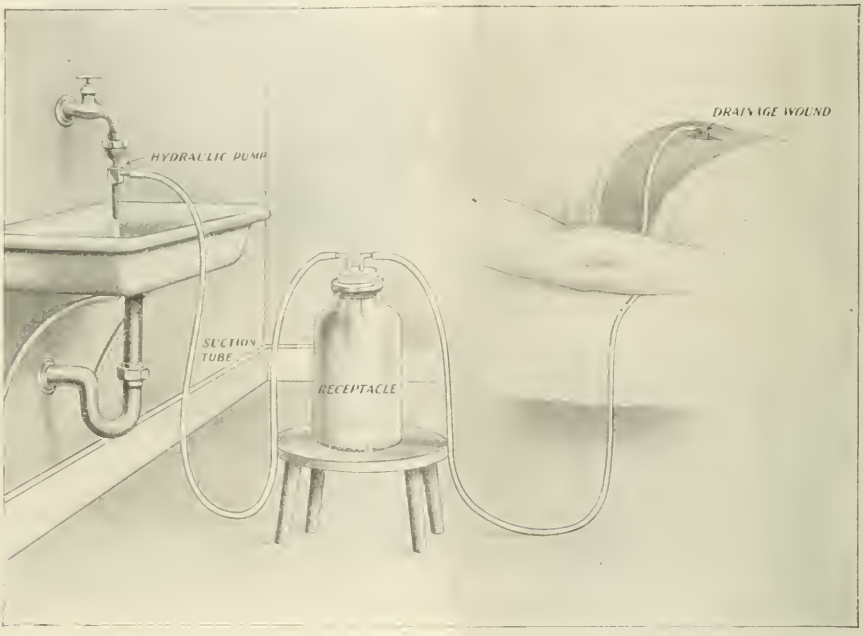

Fig. 1.

When the patient is able to get up out of bed, he is still attached to his suction apparatus, and the smaller tube is inserted far enough into the suprapubic wound to reach the summit of the bladder, and the accumulation of fluid is thus immediately withdrawn by the action of the suction apparatus.

This method works better than any previous expedient employed, but it is not always possible to obtain a constant and unvarying water pressure. Therefore, I have experimented with an electrically run aspirating pump, to be attached to any electri-

cal outlet, and also have endeavored to substitute compressed air as a means of suction in place of the hydraulic system. The trouble is, however, in all instances, when the suction tube is obstructed by the accumulation of mucus or pus, the entire pressure of the vacuum in a tank or at a pump is exerted, which is likely to be excessive, and in some cases to do harm. I have seen a hemorrhage started under such circumstances.

According to the principles of physics, if we have a vacuum of 25 inches in a tank, and an outlet valve which cuts it down to 3 to 5 inches, that is all right so long as no undue suction is exerted; but the minute unusual resistance occurs, the pressure to the total amount of the vacumm within the tank is exerted. On the other hand, most pumps which are so small as to provide only a moderate suction for all requirements, cannot do service for 24 hours in a day, and for consecutive days, without heating up.

After studying the situation out, we find the problem is to have a motor of low speed and a pump heavy in construction and also of low speed, so that both apparatus can be run continuously, day in and day out. Again, it is necessary, after setting the suction for the maximum requirements of the thicker substances that accumulate within the bladder, to provide a safety device that will blow out when the resistance exceeds a certain degree.

These requirements are all embraced in the apparatus which is here shown (Fig. 2) and which has proven its practical utility. The motor is 1/12th horse power, belted down to low speed; the pump is an inverted positive pressure blower used for air blast, of low speed, made very heavy, and heavily oiled. A small reducing needle valve is attached to the tube connecting with the drainage bottle, in which the amount of pressure is regulated, and after regulation the safety valve prevents any excess of suction. The amount of this pressure may be measured by means of a vacuum gauge. This apparatus, on account of its very heavy construction, can be run continuously without heating up. It is all enclosed in a sound-proof box, so as to avoid the annoyance to the patient that might arise from the sound of the continuous action. This may be attached to any electrical outlet, and is constructed for both alternating and direct current.

Another feature of such an apparatus is that in a ward where more than one patient requires its use, all can be attached to the same system by additional pipe connection.

The advantages of this effective means of drainage are: First, the possibility of leaving a smaller suprapubic opening than is ordinarily required; second, the constant removal of fluid blood, thus avoiding clot formation and undue discomfort and strain; third, the surfaces of the abdominal cut are kept clean, instead of being bathed in fetid urine.

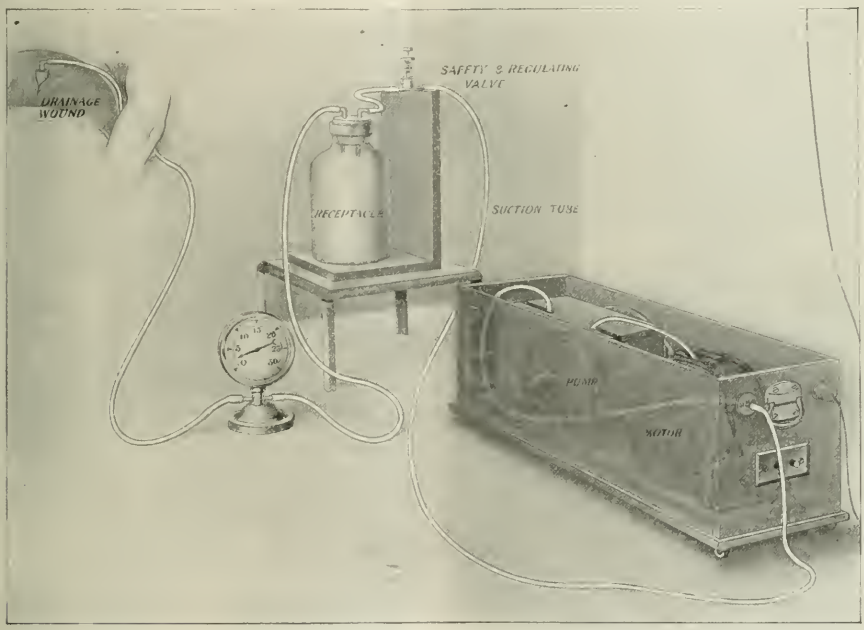

Fig. 2.

All of these advantages combine to insure a more rapid healing, with the patient out of bed in a minimum period, thus removing from the suprapubic operation, which all grant is a superior method of approach, that which, more than any other reason, has made it compare unfavorably with the perineal operation, namely, absence of adequate surgical drainage. In a large number of my cases I have found it entirely impracticable to eliminate the requirement of suprapubic drainage, notably in prostatectomy. There are some cases of stone in the bladder where the stone can be removed and drainage obtained by way of the urethra. Such cases are the exception, and not the rule. This method of obtaining bladder drainage does not complicate the management of the after-treatment by

adding to the difficulties, is really a practical solution of the main disadvantages attending the suprapubic operation, and consequently possesses real merit in expediting recovery and even in lessening some of the attendant dangers.

25 Park Avenue.

## THE DENTAL ASPECT OF ORAL INFECTION.*

By M. L. Rhein, M.D., D.D.S.,

New York.

Lecturer on Dental Pathology, Department of Dentistry, University of Pennsylvania.

The study of the anatomy, physiology, and pathology of every part of the human body, with the exception of the dental organs, is a part of the medical curriculum. These organs consist of the teeth, their lining membrane, the pericementum, the alveolar structure and the gums. They guard the vestibule of the digestive tract and their normal use is an important phase of the first scene in food digestion and assimilation. They are at different times surrounded by many pathogenic microorganisms, and any deviation from a physiological status must surely tend to interfere with normal digestion and food assimilation. Nothwithstanding the important rôle which these organs play in health conservation, the young physician starts in to practice without having received any proper instruction concerning them either in health or in disease. Consequently, without proper postgraduate study it is impossible for him to appreciate the difference between good and bad dental therapy.

I bring to the Fellows of the New York Academy of Medicine a plea for recognition of a specialty whose highest aim is to preserve the health and integrity of the portal of the digestive tract.

Bacteriology during its relentless conquest of empirical medicine has shown the mouth to be the most prominent propagating point for almost every kind of microorganism. The knowledge already obtained of the etiological relation of the dental organs to infectious diseases must surely bring the entire medical profession to a realization of the fact that their duty to the public health de-

Fig. 1.—This is the photograph of a very thin ground section of one-half of the mandible in which blind abscesses are seen attached to the ends of the roots of the first molar. The one attached to the distal root is the larger of the two. The infiltration of the septic substance through the cryptlike cells is well shown.

mands that they should obtain such knowledge, that they will at least be able to judge as correctly the merits of the dental services rendered to their patients as of services rendered through any other specialty. The dental organs, like the hair and nails, can be classed as end-organs, and consequently are very impressionable to any nutritional impairment. The alveolar portion of the jaws con-

sists of a buccal and lingual plate of bone between which are masses of bone divided into crypt-like cells filled in with a mixture of fibrous embryonal and degenerative remnants of epithelial structure. The roots of the teeth are imbedded in this structure and united to it by tendons and a membrane known as the pericementum or the peridental membrane, which in turn unites with the periosteum. Bloodvessels and nerve fibers pass through foramina at the ends of the roots and lead through the root canals to the pulp chamber which is filled with a jellylike mass of embryonal tissue. The gums are especially marked by their great vascularity. This tissue is ramified by a vast network of anastomosing capillaries and is a covering to the alveolar structure.

Septic conditions of the dental organs can be divided into three classes. First, where there is a free purulent discharge into the mouth. This may come from a sinus which has burrowed through the alveolar plate and through which is discharging an alveolar abscess emanating from a putrescent pulp. Or there may be a discharge of pus from pockets alongside of the roots of the teeth without having any connection with the pulp of the tooth. This condition is generally known as pyorrhea alveolaris. The etiology of this latter lesion is very varied. In all forms of malnutrition this pathological state may become a very marked symptom, depending largely on how much the resistance of the individual has become impaired.

Realizing that we are dealing with end tissue it is not surprising that the first symptoms of any form of malnutrition should be manifested around the gums with its vast network of anastomosing capillaries. "It is not unreasonable to suppose that the chemical change that takes place in the blood under such circumstances varies according to the organ involved and the nature of the malady. This accounts for the great difference in the clinical picture of the gums in different forms of pyorrhea alveolaris."* A minute study of the different pictures to be found in the mouth in different types of disease will not only be found an invaluable aid in differential diagnosis, but frequently can be utilized as the means of making a positive diagnosis of some grave disease long before any other symptom manifests itself. There is another type of pyorrhea much more frequently met which is due to trauma and localized irritation. The destruction of the first line of defense in such

*Read before the New York Academy of Medicine, February 5, 1914.

*Rhein, M. L.: *Dental Cosmos*, November, 1812.

cases is mostly produced by improper dental operations. Another cause is found in the impeded eruption of third molars. Purulent exudations in the mouth also come from impaired tonsils and from the pharynx. Exfoliating pieces of necrotic

FIG. 4 shows an abscess of an upper lateral and an upper central incisor caused by imperfect root fillings which permit of seepage through the end of the root. The pus has burrowed its way to the neck of the central where it empties into the mouth. A probe is seen passing through the sinus to the abscess.

FIG. 5 shows two abscessed upper incisors.

bone or roots are also frequent etiologic agents.

The effect upon the rest of the body of the constant swallowing of purulent matter has been the subject of much discussion. Science has today practically eliminated the idea that the gastric juice is a barrier to the passage of bacteria and pus from the stomach into the intestines. "Undoubtedly most of the swallowed bacteria are destroyed, not by any of the digestive secretions, but by competition with the normal intestinal bacterial flora which has preempted the ground when the nutriment is after all limited in quantity. When, however, instead of merely swallowing the ordinary bacteria mixed with the food, the individual is constantly swallowing certain amounts of pus, an entirely different problem presents. The nature, virility, and number of the microorganisms must have a strong influence as to their ability to overcome the surface immunity of the digestive tract. Many forms of diseases of the stomach and intestines are possible. By means of their development in the digestive tract such bacteria are very easily absorbed in the circulation

FIG. 6 is the second roentgenogram of these teeth after the pulp tissue has been removed. Gold wires have been placed in the root canals and they give evidence by penetrating through the end of the canals that they have been cleaned to their very ends.

FIG. 7 has been taken after the zinc electrolysis has been applied to the alveolar structure around the ends of the roots and the root canals hermetically sealed, showing encapsulation of the ends of the roots.

and pass into the lymph spaces. After this fortress of the body has succumbed, the bacteria with their poisonous products appear to be irresistibly drawn to the most vulnerable of the vital organs. Medical literature is replete with citations of numerous forms of disease due to pyogenic bacteria which are traced to this one source."*

The second class, pericemental abscesses, are those cases where pericemental tissue becomes infected from some form of pyogenic bacteria. In these, the vitality of the pulps of the teeth remains intact. While they are supposed to be rarely met, it is more probable that the attending dentist has failed to make a correct diagnosis of the diseased area. This infection is much more common than

FIGS. 8 and 9 show microphotographs of sections of pulp tissue in which calcareous deposits have strangulated the circulation in the pulp. Normal pulp tissue is almost obliterated by this hardened calcareous abnormal structure. Especially in multirooted teeth this is the greatest obstacle to cleaning out the canals to their very ends. The persistent application of sodium and potassium will accomplish the desired result.

is appreciated at the present time. The most rational theory of its etiology is that enamel germs of the teeth have left sufficient epithelial cells in this membrane to become an attractive nutriment for pyogenic bacteria. After some time, infiltration causes the establishment of a sinus reaching generally to the neck of the tooth, and in this state is only too frequently diagnosed as an ordinary pyorrheal pocket. The treatment of pericemental abscesses is very poorly understood at present.

*Rhein, M. L.: *Dental Cosmos*, November, 1912.

Its differential significance must, however, not be overlooked.

I have reserved for the third class the most important type of mouth infection, the granuloma or blind abscess attached to the end of a root and

Fig. 10 shows an upper molar where on account of such calcific matter the dentist failed to penetrate beyond the entrance to the three canals. Infected areas are noticeable at the ends of the roots.

Fig. 11 shows the same root after the old filling has been removed and by means of instrumentation and the use of sodium and potassium the lingual root has been entirely explored, the distobuccal almost entirely, but the mesiobuccal only a short distance. The picture demonstrates that, on account of the curvature of the mesial root, it is necessary for the operator to remove sufficient tooth structure to permit the wire shown here to enter the canal as near by as possible to the mesiobuccal angle and so, for operative purposes, obliterate the curvature of this root, converting it into a comparatively straight root canal.

which grows in size at the expense of the osseous structure of the alveolus. The important feature of these cases rests in the fact that there is no mouth outlet for the purulent matter, which is therefore confined to a small area in the alveolus. Nature attempts to limit the size of a granuloma by means of a thick fibrous envelope, which defends the adjacent tissue as much as possible from infiltration. Notwithstanding this defense, a gradual absorption of the bacteria or their toxins is going on continuously. "The pathogenic bacteria escape from the local foci of infection by penetrating into the surrounding pervious lymph spaces and capillary vessels, into which they push, through continuous growth, or are carried by their own motility or by motile phagocytes."* The cryptlike cells of the alveolus make the infiltration of these products very easy when once they have passed through the envelope of the granuloma.

The small amount of inflammation and the quiescence of these abscesses is most likely due to the low type of virility of the bacteria present. Patients may have a number of such abscesses without experiencing the slightest symptom of discom-

Fig. 12 shows the gold wires in all the canals after the next operation and after the entrance to the mesial canal has been brought much nearer the approximal side of the tooth.

Fig. 13 shows the tooth at the completion of the root fillings.

fort in the infected region. It is to be regretted that there is not sufficient time to detail clinical notes of these cases, but it is worthy of note that on bacteriological examination the majority of cases show the presence of *Streptococcus viridans*. That the attack of this low type of organism is especially directed against the heart is well understood. If these observations are correct, the insidious nature of these abscesses and the grave danger of

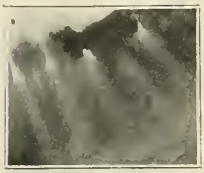

Fig. 14 shows good root fillings completed in a lower molar.

Fig. 15 shows good root fillings completed in an upper molar.

producing one of the types of endocarditis cannot be minimized. Blind abscesses have been known to remain quiescent for many years and then suddenly to develop so great an activity as to readily change into the ordinary type of alveolar abscess with a sinus opening into the mouth. Rosenow's recent demonstration of the possibility of changing under certain conditions, one type of streptococcus for that of another, would readily account for a blind abscess suddenly changing from a quiescent character into one of great activity. These abscesses must be differentiated from the dental cysts found in this region and which are found devoid of the presence of any pyogenic organism.

The Roentgenogram has disclosed the fact that these infections are exceedingly common. The infection of any portion of dead pulp tissue is the immediate exciting cause. It may occur in a tooth where caries is followed eventually by death of the pulp. Inflammatory action and subsequent death of the pulp under the most skillful of dental operations is always a possibility. A traumatic condition producing a rupture or strangulation of the pulp where it enters the root canal is not infrequent. The most prolific source of blind abscess comes from imperfect dental operations involving the pulp of the tooth. Under the guise of dental aid the patient is inoculated with the toxin that left untreated must result in the gradual destruction of the heart function.

That the physician is ignorant of the large number of severe diseases arising from bad dentistry is well illustrated by the fact that so many cases of this kind are found in the mouths of physicians

Fig. 16 shows a series of alveolar abscesses of lower front teeth with their sinuses opening at the necks of the teeth. This case was, for years, erroneously diagnosed and treated as pyorrhea alveolaris. Such erroneous diagnosis is being constantly made by self-styled pyorrhea specialists.

themselves. With our present knowledge there is no excuse for this condition, and when once understood by the mass of physicians, neglect that can be followed by such grave results, will no longer be tolerated. Scientific treatment of pulps and

*Rhein, M. L.: *Dental Cosmos*, November, 1912.

root canals should leave a result in which septic infection is impossible. In the small percentage of cases where this end cannot be attained, the tooth should be extracted. The technique of such work requires a very delicate procedure and necessarily great skill, and frequently the expenditure of hours of labor.

Fig. 17 shows a case of pericemental abscess surrounding the lower half of the mesial root. The vitality of the pulp had not been impaired.

The pulp, for operative purposes, can be compared with the marrow of the long bone and all stages of its treatment should be carried on under the most careful aseptic surroundings. Every particle of pulp tissue must be extirpated and the canals opened to the very ends of the roots. Only since the Roentgenogram has been at our disposal,

Fig. 18 shows blind abscesses imprisoned under roots used in bridge work. There is no external evidence of inflammation nor any discomfort noticed by the patient.

has it been possible for the dentist to know whether operative measures of this nature have been successfully completed. Consequently therapy in this field should invariably be accompanied by Roentgenogram proofs. The removal of pulp tissue on account of the curved nature of so many roots, together with calcareous degeneration in so many cases, makes the operation one that frequently requires numerous hours of the most careful manipulation. Only when a fine wire can be introduced to the very ends of each root canal can there be a certainty that the root is ready for the next step in the operation, which consists in sealing the lower portion of the canal with a filling which homogeneously seals every nook and crevice in the canal and if possible encapsulates the end of the root. This filling material should have no properties which can possibly irritate the tissues in the apical region. The ends should, however,

Fig. 19 shows one of the very common types of blind abscess when the pulp has died as the result of placing a gold shell crown over the root of the tooth. In such cases there generally is no discomfort.

Fig. 20 is a roentgenogram taken a few months ago, showing a similar gold shell crown over a lower bicuspid with a well marked granuloma at the end of the root. The tooth was subsequently extracted under the direction of Dr. Henry James. Cultures made by him from this granuloma produced the *Streptococcus viridans*.

not be sealed whilst any infected area of the alveolus is present. All such pathogenic tissue must be removed. This can be done either by a surgical curettage or by electrolytic therapy. As long as the root itself has not become necrotic, the application of zinc electrolysis will clean out the infected zone. The Roentgenogram has shown so many cases of restored alveolus after this treatment that its efficiency as a radical cure for such necrotic areas appears to be thoroughly proven. After the end of the root has been hermetically sealed and the canal filled, the pulpal end is covered with an antiseptic cement of which oxychloride of zinc cement is a good example.

The faulty root canal work, done by the most skillful operator, without the aid of the Roentgenogram has made this aid an absolute necessity from the commencement to the completion of these operations. By means of this view of the alveolus, roots whose curves make the reaching of their ends appear almost impossible, can be entered at such a point as to practically eradicate this curvature.

If the final picture should show an imperfect operation, it is imperative that the root filling be removed and replaced by one without defect.

The illustrations (shown at the meeting as lantern slides), together with all the evidence in the matter under discussion should cause the medical profession to halt and consider if they are doing their duty for the protection of the public health.

It is a professional neglect to further defer action. No so-called special field taught in the medical colleges by specialists can show so great an etiological bearing on infections involving the health of the community. Hence I believe that no one should be graduated from a medical college

Fig. 21 is a roentgenogram taken two years after amputation of the end of an upper central incisor. New alveolar structure is seen filling in the vacant space.

Fig. 22 is a roentgenogram taken eight years after treatment of very severe alveolar abscesses by means of zinc electrolysis. The new alveolar structure in the previously diseased area is unmistakable.

without having received a course of instruction and passed an examination in the principles of stomatology. Then only, will physicians as a whole be trained to take their proper places as judges to determine if the community is receiving the benefits of scientific dentistry, which will not only increase the comforts of the individual, but operate as a material factor in increasing the longevity of those fortunate enough to secure its services.

## A CASE OF SPOROTRICHOSIS WITH MULTIPLE LOCALIZATIONS—IMPORTANCE OF THE *X*-RAY EXAMINATION TO DETERMINE THE FOCI.

By FRANCISCO DOMINGUEZ, M.D.,

HAVANA, CUBA.

PROFESSOR OF TOPOGRAPHIC ANATOMY OF THE UNIVERSITY OF HAVANA; HONARARY FELLOW OF THE AMERICAN ELECTRO-THERAPEUTIC ASSOCIATION; TITULAR MEMBER OF THE MEDICAL RADIOLOGIC SOCIETY OF PARIS.

In the month of December of last year I was called upon by a colleague to examine with *x*-rays for diagnostic purposes one of his patients who had been sick six months.

He was a powerfully built white man, 54 years of age; had gone into the interior of the country six months previously with the object of purchasing tobacco, and had tasted various leaves in different plantations. While doing this work after about eight days he felt indisposed, with general malaise, slight chills at frequent intervals, and what constitutes a

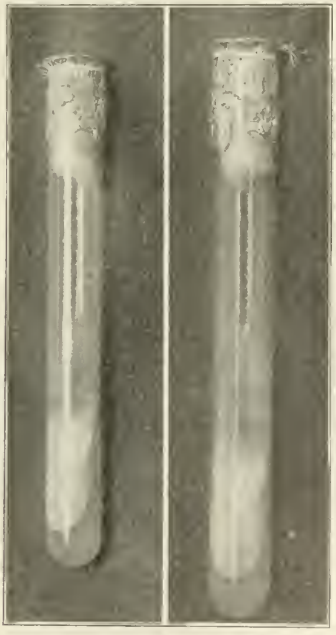

Fig. 1.

very important point as stated by the patient, very slight fever, temperature only reaching 38° C. during the 24 hours. In this condition he remained 50 days and as he did not improve he decided to come to Havana. On examination my colleague found a pneumonic focus circumscribed to the central portion of the left lung, easily demonstrated by auscultation and percussion, and a slight daily expectoration that greatly increased on the patient's lying down. This expectoration, typical of hepati-

Fig. 2.

zation of lung, at times streaked with blood, was coincident with the appearance of the disease. The temperature never went higher than 4 or 5 tenths above the normal, except on the day noted when it reached 38° C.

My colleague made the diagnosis of a pneumonic focus and in this sense had the sputum examined. He was greatly surprised at not finding either the Talamon Frankel, the Friedlander, or the Koch or Pfeiffer bacilli; nevertheless the patient continued to present the same symptoms, the same expectoration, and my colleague in view of lack of etiological data, began to entertain the possibility of malignant tumor of the lung. It was for this reason I was called in, thinking that perhaps the *x*-rays would throw some light on the subject.

On first view of the patient I must confess that my attention was drawn to the almost total absence of fever during the whole course of the disease, which otherwise presented all the symptoms of pneumonia, the sputum being pathognomonic notwithstanding, there were no bacilli of Koch, Friedlander, or Pfeiffer; and furthermore to the chronicity of the disease, as the patient had been sick for six months.

I stated to my colleague that we would of course make the radiograph, but that to my mind the clinical aspects of the case did not resemble those of malignant tumors of the lung hitherto seen by me. Aside from other clinical considerations, in these lesions there is little or no expectoration, while in the present case expectoration sometimes was so abundant as to appear almost like vomiting. On the following day I made a radiograph while the patient's physician had the sputum examined with a view to cancer cells, and I had a similar examination of the sputum made with a view of finding spores, inasmuch as in my opinion the case materially differed clinically from all classical cases of lobar pneumonia, and furthermore I had in mind a similar case that I had seen together with Dr. Raimundo Menocal a few days previously.

On the following day I made a radiagraph and I found the lesion at the spot clinically localized by my colleague. This lesion is clearly seen in radiograph No. 1.

The patient brought the sputum collected during the night. At first glance a large number of spores were observable in the original preparation. These were placed in peptonized and malted agar, giving rise to the rapid growth seen in Figs. 1, 2, and 3.

Dr. Menocal's report, as result of his examination, is that we have to deal with a case of *Endomyces albicans virillemen*, which appears in the form of branching cylindrical filaments about 5 mikrons in length, composed of superposed cells touching one another. Between these plants may be seen very refractive ovid cells 5 mikrons in length. The cultures give rise to filamentous and globular forms.

In view of the pulmonary lesion having once shown its sporular origin, the therapeutic indication was clear. Iodide of potassium was given in doses of 4 or 5 grams per day. The above is not the most interesting part of this clinical case, as we might assume knowing the disease and its treatment.

The data given by the patient as to his having been taken sick while testing tobacco leaves for a purchaser, remained fixed in my mind; these leaves had suffered no other preparation besides cutting, drying, and packing in bales for sale to the trade. I requested my patient to obtain for me some samples of the leaves from the places and the lots that he had tested and of these I planted several pieces in peptonized and malted agar, when I was gratified to see several colonies sprout up. Among them there was one which morphologically resembled and microscopically was proven to be *Endomyces albicans*, causative agents of the pulmonary lesion of our patient. The nature of this work does not permit me to speak at greater length on the existence and propagation of these spores by the leaves of tobacco. I shall make a report to the Academy of Medicine of Havana on the variety and number of spore colonies to be found in the leaves of green tobacco.

FIG. 3.

The patient followed the iodide treatment and rapidly improved. A month later I made the second radiograph in which the decrease of the lesion may be observed. This decrease in size has been followed by lessening of pain, disappearance of elevated temperature, sputum diminished, and finally, as soon as he began to take the iodides, the appetite reappeared and the patient began to gain weight.

Toward the end of January, when the patient was almost well, he went to see Dr. Soto to consult him on account of pain in the right ear which had been troubling him for five days. My colleague observed that the tympanum was dull, white in color, convex in the inferior segment. There was very little pain on pressure, and the patient was unable to hear the tick of the watch either by the air or bone transmission. After the use of warm carbolized glycerin instilled into the ear the pains disappeared within three days, but other pains radiating forward, paroxysmal in character, persisted in the right temporoparietal region. The patient also complained of vertigo. There was no tumefaction over the mastoid, nor sensibility over the apex or the antrum. The tympanum was not red or sensitive and there was no fever. On paracentesis of the tympanum a drop of white pus was discharged. The gauze withdrawn on the following day was pretty well stained with whitish pus. Pain and suppuration decreased, and four days after the paracentesis, the patient could hear a watch at a distance of 4 cm.

Eight days afterwards Dr. Soto was again obliged to open the tympanum and let out some more whitish pus. The drum again closed in about eight days, pains still persisting in the temporoparietal region. Under these circumstances, my colleagues, surprised by the existence of a suppurating otitis media with no reddening of the drum, no fever, no tympanic sensibility, no mastoid reaction, in spite of its duration, with persistence of atypical pains, endeavored to ascertain the nature of the trouble and discovered that the patient was still suffering from a pulmonary lesion diagnosed by us as of sporular origin (*Endomyces*). The sputum, though lessened in quantity, still persisted.

Fig. 4.

Taking the above into consideration and suspecting the possibility of an otitis media produced by the same spores, the lesion being caused by direct infection of the middle ear through the Eustachian tube, on March 6 a culture was made in Sabouraud's agar of the pus from the cavity, and the laboratory reported eight days afterwards that it was identical with the organism found in the lung of our patient.

Under the impression that the patient had completely recovered he was again brought to me by the colleague who originally brought him. He stated that there was no fever, but that the appetite had

decreased and the patient was tormented by headaches and insomnia. Patient's despair was graphically described by him when he said that "life was unbearable in this condition." In view of the gravity of the situation I made a radiograph of patient, laying him on his right side, employing an instantaneous Lumière plate on Sinegran chassis.

Radiograph No. 3 was the result of this examination. In it I can observe a complete darkening of the mastoid and, furthermore, a dark area two fingers' breadth behind and two above the external auditory meatus. This was the center of the new focus. There was absolutely no doubt the new lesion had appeared in the same manner as the others without giving rise to febrile disturbances, its symptoms being limited to headaches and insomnia.

Fig. 5.

In view of the dark shadow I did not hesitate to localize the lesion as extradural and I thought the focus to be of otic origin, although the extension had not occurred through the diploë. As there is no diploë in the squamous portion of the temporal, I believe an opening had occurred on the base of the petrous portion and that this extradural focus was its result.

Dr. Presno lost no time in operating. On the following day he placed a trephine over the center of the dark shadow as marked by the radiograph, and on penetrating through the bone there was an abundant flow of pus of about one ounce. The pus extended towards the base of the petrous portion. The cavity was first washed out with peroxide of hydrogen, followed by weak solutions of iodine, dressed, and patient put to bed. On the following day all the symptoms had improved and fifteen days later the patient was discharged cured.

Cultures of pus were made this time as on all previous occasions and the result was always the same, giving a pure culture of *Endomyces albicans*.

My purpose in relating this interesting observation is to demonstrate the importance of the new methods of investigation as aids to the clinician. Without the aid of the laboratory and the *x*-ray, this case would never have been cleared up, so far as its nature and localization are concerned.

The etiological diagnosis was made by laboratory methods, the *x*-ray aided us in the localization, especially so in the cranial localization which was all the more difficult to establish in view of the fact that we were dealing in this case with what practically constitutes a new clinical type, that is to say, a suppurating focus, not giving rise to febrile reaction and having a new pathology. The physician now on the alert by careful study of its modifications will be able to establish some new clinical entities.

# THE LIQUOR QUESTION IN MEDICINE.

By EDWARD HUNTINGTON WILLIAMS, M.D.,

MONTCLAIR, N. J.

FORMERLY OF THE NEW YORK STATE HOSPITAL SERVICE.

At a recent meeting of the World's W. C. T. U. doctors were severely criticised for using alcohol in any form in their practice, and it was seriously suggested that efforts be made to have a law passed forbidding them to do so. Of course, the implication in such a suggestion, aside from the obvious one that physicians are not the best judges of how medicine should be practised, is that medical men are opposed to the cause of temperance. From the printed records of their teachings, however, it should be apparent, even to very confirmed faddists, that physicians, individually and collectively, have always been ardent advocates of temperance. Every text book dealing with the causes of disease points out the evils of alcoholic excesses. Indeed, the medical textbooks now in existence probably constitute the greatest temperance library in the world. The methods of the creators of this great library may be questioned, but not their motives.

Moreover, physicians are ready to accept any method of combating disease if such method can be shown to be effective. So that if the various organizations that advocate prohibitive liquor legislation could show encouraging results there is no doubt that medical men would look less askance at their methods.

These advocates of prohibition, through such organizations as the W. C. T. U., the Scientific Temperance Federation, Anti-Saloon League, etc., have had a quarter of a century in which to demonstrate the worth of their theories in actual practice. Largely through their efforts all States have passed laws "requiring the study of scientific temperance," physiology and hygiene, and in some States at least the law requires oral teaching of these two last branches for "children as yet unable to read." Furthermore, prohibitive legislation against the liquor traffic has increased to such an extent that at present fully one-half the people of the country are said to be living in what is claimed to be "dry" territory. So that all school children are now taught the dangers of excessive alcoholic indulgence, and half the adult population of the country is forbidden to obtain liquor except by unusual and complicated methods of barter. Surely such sweeping legislation ought to get results.

But in the face of this legislation we find at the present time that more than twice the amount of whisky is consumed annually in the United States than was consumed seventeen years ago.[1] More liquor of all kinds is consumed per capita to-day than ever before in the history of our country. And the diseases that are known to be caused by alcoholic excesses appear to be increasing rather than diminishing. Moreover, the Government statistics[2] for the last census period show that certain diseases which are attributed to excessive alcoholic indulgence, directly or indirectly, have increased more in the group of States where prohibitive legislation existed at the close of the period, than in the United States as a whole.

Thus, according to this report, there was a gain of 4.4 insane persons per 100,000 population, committed to the institutions of the country during the census period. But during this same period the gain in the eight prohibition States was 7.3 per 100,000—almost twice the gain in the country as a whole. Moreover, the greatest gain in any State, with a single exception, was in prohibition Maine, where the number of insane increased 21.2 for each 100,000 inhabitants, while "wet" Nebraska holds the record at the opposite extreme with a decline of 27.6 per 100,000 during the same period. When we add to these facts that the record for homicides in 1912 went to Memphis, in prohibition Tennessee, with 64.3 homicides per 100,000 population, as against license Philadelphia's 1.4[3] (the lowest record of the year); that Bangor, Me., a prohibition city for thirty years, has a record of arrests for drunkenness in that year of one to every nine inhabitants,[4] and that Kansas, the veteran standard bearer for prohibition, has more insane than seventeen of the "wet" states scattered across the country, and more paupers and convicts than her unregenerate neighbor, Nebraska,[5] the results of prohibitive legislation are not encouraging, to put it mildly.

"Moderation is no definition of temperance," said an enthusiastic feminine speaker at the World's W. C. T. U. meeting a few weeks ago. She might have added, "Neither is prohibition."

This record of the increase of certain diseases and conditions influencing diseases flourishing most in territories directly under the rule of prohibition, without any evidence that there is a compensating decrease of any diseases in such regions, does not tend to increase the confidence of thoughtful physicians in the methods employed. Indeed, some of the unscientific, "scarehead" methods used by some of the societies interested in promoting prohibitive legislation depart so far from established methods of presenting scientific truths that they repel rather than attract most medical men.

The term "unscientific methods" includes such things as stating only one side of a case when the facts on the other side are available, presenting as facts things still open to question, and accepting statements without due scientific caution.

For example, in a recent pamphlet[6] prepared by the Scientific Temperance Federation of Boston the statement is made that "alcohol carries off 1,662 adults every nine days all the year round in the United States." As a matter of fact the document upon which this assertion is based [7] makes no such dogmatic statement, but offers the "estimated" death rate as a tentative approximation of the numbers, which is quite a different matter. Any estimate must necessarily be only tentative, since the facts at our command do not warrant dogmatic positive statements given in exact figures.

It has been repeatedly stated by such men as the late Dr. J. S. Billings, and Mr. John Koren, both of whom were actively engaged in the work of investigating the subject by the Committee of Fifty, that there are no reliable data on the mortality of alcohol in the United States. For the causes of many diseases are still unknown, and what appears to be an etiological truth to-day may be branded as false to-morrow by some fresh discovery.

The recent discovery of the cause of paresis by Drs. Moore and Noguchi[8] offers an example, and it so happens, applies directly to the case in hand. Paresis is included in the "tentative approximation" of deaths from alcohol, yet we know now that the disease is caused by the specific germ of syphilis. Paresis is uniformly fatal, represents some 12 per cent. of all forms of insanity, and figures conspicuously (about 7,000 deaths annually*) in the death

*These figures are based on the Twenty-fourth Annual Report of the New York State Hospital Commission, Albany, 1913.

rate among the quarter of a million insane persons in the United States. It is obvious, therefore, that the discovery of its cause alters very materially, even tentatively approximate death rate estimates. It also confirms the statement of Dr. Billings and Mr. Koren, and refutes any dogmatic statements made hitherto as to the number of deaths from alcohol which included paresis as an alcohol-produced disease.

Another statement in this same publication is an example of the lack of scientific caution exhibited by lay enthusiasts in accepting as facts what clinicians would regard only as probabilities or possibilities. Thus, an estimate is given that "30 per cent. of the deaths from Bright's disease" are caused by alcohol. We may overlook the indefiniteness of the term "Bright's disease" (although a physician would hesitate to use the term in print without explanation), but the statement suggesting the exact percentage of deaths caused by "Bright's disease" is much too dogmatic, for clinical observations and recent post-mortem findings do not warrant precise statements about etiology in this class of diseases.

Thus, "Fahr in a series of 309 autopsies on chronic alcoholics" found that "chronic nephritis caused the death of but eight cases, and was less commonly noted than in hospitals with patients of a better class." That "arteriosclerosis was apparently less common than in bodies of non-alcoholics of corresponding age." And "Baumgarten[9] found cirrhosis of the liver in only 6 per cent. of autopsies among hard drinkers," all of which seems to raise the question as to whether rich foods, sedentary habits, mental states, etc., do not play a part sometimes attributed to alcohol, and perhaps explains the opinion of Dr. Emery, of the Manhattan Life Insurance Company, that "a man who is an overeater is not likely to live as long as some excessive drinkers."

The examples of positive statements just given show the lack of scientific caution exhibited by some of these partisan organizations in their literature. Sooner or later their methods are sure to react upon them—as we may judge by general results and create skepticism as to the value of any of their statements or their methods.

Another method that is open to criticism—one that suggests the authorship of politicians rather than that of scientists—is that of taking only a few specific cases and presenting them so that they will impress the uninitiated as representing accepted general truths.

It is quite possible, indeed, that the originators of this plan, rendered myopic by enthusiasm and lacking scientific training and clinical experience, believe that their isolated examples do really represent general truths. But this sort of ignorance will not tend to increase the confidence of serious investigators.

Thus, on a chart[11] done in colors the results of an investigation made by Prof. Demme[10] in Berne the number of defective descendants of ten "very temperate" and ten "intemperate" families are indicated. The summary of the results shows that only 17.5 per cent. of the descendants of the intemperate families were normal, while there were 82 per cent. normal descendants of those classed as the very temperate families.

The facts given in this chart are interesting in themselves. But no scientist would use them, either in a general way or as pointing to any fixed relation between alcoholism and mental defects, without offering for comparison the findings of the Francis Galton Laboratory for National Eugenics, made on a much more comprehensive scale at a later date and under the direction of Prof. Karl Pierson, an investigator of first magnitude in this field of research.

For the number of families examined by the Galton Laboratory investigators were counted in hundreds, not merely tens, the investigators themselves were trained observers, and from their character no one can accuse them of prejudice in favor of alcoholism. The epitome of their findings, quoted from the Memoir,[11] is as follows:

"The mean weight and height of the children of alcoholic parents are slightly greater than those of sober parents. * * *"

"The general health of the children of alcoholic parents appears on the whole slightly better than that of sober parents. Parental alcoholism is not the source of mental defect in offspring. The relationship, if any, between parental alcoholism and filial intelligence is so slight that even its sign cannot be determined from the present material."

In short, these findings show utterly different results and convey an entirely different impression from the Demme chart. Many persons will, of course, question the import, if not the facts, of the Galton Laboratory observations. But no sincere seeker for truth can disregard them to the extent of exhibiting the Demme chart alone, or any similar chart, without laying his methods open to just criticism.

The findings of the Galton Laboratory in the same field of investigation, the mortality of children of drinking mothers, also illustrates the necessity of exercising extreme caution in jumping to general conclusions from the observation of a few special cases.

Two specially prepared and copyrighted charts, showing the number of children of alcoholic mothers that died before reaching two years of age, have been exhibited in various places recently by one of the "scientific" temperance societies.[12] On these charts, in which the dead babies are represented as dolls in black dresses, while the living are dressed in white, the death rate among the children of drinking mothers is given as 55 per cent.—fifty-two mournful little black dolls grouped in the center of the picture; while on a similar chart the mortality of children of sober mothers is shown to be 23 per cent.

In an investigation similar to the one forming the basis for the doll chart, but conducted on a much more comprehensive scale, the Galton Laboratory investigators found the death rate among the children (of all ages) of the Manchester mothers amounted to 26.5 per cent. of the children of sober mothers, while 33.8 per cent. of the children of drinking mothers died.

According to both these reports, then, it appears that the alcoholic mother will have more of her offspring die in childhood than will the sober mother. But there will be no such wide difference as given in the black doll chart. Moreover, the Galton investigators found that the drinking mothers evened up the net results by bearing more children than their sober neighbors—a statement that should be of particular interest to one of the eminent ex-officials of our country who is greatly interested in the race suicide problem.

When we consider certain demonstrated facts about liquor legislation, liquor consumption, and

baby mortality, it becomes apparent at once that a study of the subject of relationship between these conditions, if any, will lead to curious and bewildering complications. During the last quarter of a century 50 per cent. of the country has become prohibition. During this same period the amount of alcohol consumed has more than doubled; and meanwhile the death rate among babies has steadily declined. So that at present we have more prohibition, more liquor, and more living babies. It is obvious, therefore, that any statement that suggests any single cause as having produced this apparently anomalous condition is necessarily at once open to challenge.

The advocates of prohibition are responsible beyond a doubt for the increase in prohibitive legislation; the people as a whole are responsible for the increased consumption of liquor; and doctors must be credited for the reduction in infant mortality. So that we have at least three factors for consideration.

However, without attempting the difficult task of solving so complicated a riddle, we can put a finger upon one fact that undoubtedly has considerable bearing upon the increase of certain diseases attributed to alcohol. This is that the consumption of the injurious spirituous liquors has increased more than that of the milder beverages,[13] and owing to the relatively small bulk of such liquors, seem to be used in greater quantities proportionately in prohibition territories. In their vilest, most deadly fusel-oil form they constitute the principal ammunition of the ubiquitous "suitcase peddler" in the "dry" regions. And no one questions that these deadly concoctions influence very materially the mortality statistics.

I have before me a series of charts issued and widely exhibited by one of the societies referred to a moment ago. Some of them represent universally accepted truths. Others present facts that may be accepted as representing certain phases of the liquor question. While still others could not be accepted by physicians as giving a fair presentation of the subjects they represent. As a whole they show that the authors lack the knowledge of practical psychology, which is the keystone of every physician's success, and have not caught the spirit of modern educational methods. For they aim to teach by gross exaggeration—a method that most educators condemn as archaic.

In effect the promotors of radical liquor legislation, or at least the sincere ones not dependent upon political constituency, assume that most men would become alcoholics if given free access to drink. Yet most men do have such free access, and very few of them become alcoholics.

To clinicians and students of heredity, however, it is becoming more and more evident that the really important factor in producing insanity, alcoholism, drug psychoses, etc., is a deeply seated hereditary defect, not merely the result of environmental conditions. In short, that the alcoholic is a person quite different from the man who occasionally takes a glass of beer. Dr. Thomas W. Salmon has expressed this view in the single sentence: "In a world of drinkers the alcoholic is an abnormal type."[14] Dr. M. J. Rosenau expresses the same sentiment in another way: "It is necessary to recognize that what may be inherited is not the result of alcoholism, but rather the disposition that led the parent to become alcoholic."[15] And the Galton Laboratory offers the same conclusion in the sentence, "If, as we think, the danger of alcoholic parentage lies chiefly in the direst and cross-heredity factors of which it is the outward and somatic mark, the problem of those who are fighting alcoholism is one with the fundamental problem of eugenics." It also expresses the fear that "it will be long before the temperance reformer takes this to heart."

The recently organized societies for promoting practical eugenics are based on such conceptions of the relationship between heredity and disease. And these organizations are just as pronouncedly advocates of temperance as the older and more intolerant societies, even though they do not advocate radical legislation. Like the older organizations, they attempt to "strike at the root of the evil," but, unlike them, they distinguish between roots, and branches and twiglets.

The method of attempting to suppress any vice by trying to keep it under lock and key has never proved effective. For perverse human nature seems to crave the thing forbidden it, and will find ways of satisfying the craving. It is also a human failing to court mysterious dangers that are painted too black—a thing that poets and physicians discovered long ago. And laws that are formulated without due consideration of these fundamental elements of human nature are destined to failure in application. Here is a plausible explanation of why radical legislation has failed to check the steadily rising tide of alcoholism.

In outward form, at least, the methods of the older "uplift" societies of attempting to teach by exhibiting charts, resembles the methods adopted by the newer societies. In a general way many of their charts are similar to the excellent ones prepared by such organizations as the National Committee for Mental Hygiene, for example. Similar, but with one radical difference—they are open to challenge. And thoughtful physicians, at least, have learned to look askance at any method that will not stand the acid test of close scrutiny.

# THE PRESENT STATUS OF THE NON-OPERATIVE TREATMENT OF BENIGN AND MALIGNANT GROWTHS, AS SEEN AT THE CLINICS ABROAD.

By SAMUEL STERN, M.D.,

NEW YORK.

RADIOTHERAPIST TO MT. SINAI HOSPITAL, AND CHIEF OF THE RADIOTHERAPY DEPARTMENT, MT. SINAI HOSPITAL DISPENSARY.

WITHIN the last two or three years, so many glowing reports have appeared from the clinics abroad, in connection with the non-operative treatment of benign and malignant growths, that I decided to go over and see the work done for myself, and if convinced, to copy their technique. The object of this paper is to give a brief account of what I saw at the most important clinics I visited.

For convenience sake, I will speak of the benign growths first. The chief of these that have occupied our attention for some years are the uterine fibroids. As we know, the Roentgen-ray treatment of uterine fibroids has been going on for quite some years, but it is only within the last four

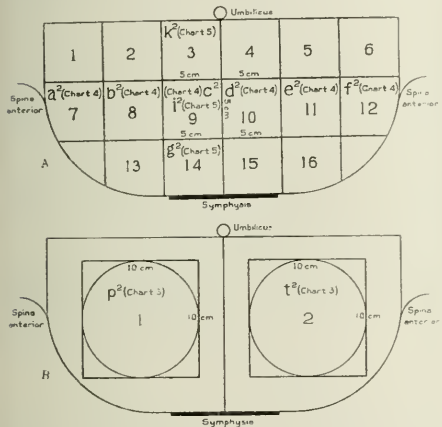

Chart 1. Fig. A shows how with the old two-field method the extent of area irradiated could not be more than about 200 sq. cm. Fig. B shows how by dividing this area into small fields the extent of irradiation is doubled, brought up to 400 sq. cm.

or five years that the subject has been given really serious attention.

One of the first men to take up the subject in a routine systematic way was Albers-Schönberg. His technique was to divide the uterine ovarian region into two or four fields, and to give each field in divided doses a quantity of ray amounting to about 10 X between each intermenstrual period.

His results were fairly satisfactory, but there were about 20 or 30 per cent. of cases, chiefly of the submucuous variety, in which nothing could be accomplished with this mode of treatment.

Two years ago at Dr. Brettauer's and Dr. Frank's suggestion, I took up the treatment of these cases, followed up Albers-Schönberg's technique, with some slight modification, as to filters, and found that in the 75 cases treated during the past two years the results were about the same as that published by Albers-Schönberg.

About three years ago, Krönig and Gauss of the Freiburg school, developed a new technique for the treatment of these cases, the chief features of which are: (1) Dividing up the abdominal, dorsal, and gluteal regions into a large number of small fields. (2) Crossfire administration of the rays through these fields, enabling us to administer very large doses of *x*-rays to the uterus and ovaries without any danger of dermatitis. (3) The use of rays of certain degree of penetration. (4) The filtration of all rays through 3 mm. aluminum. (5) Massive doses.

With the improved technique they have succeeded in curing 100 per cent. of their cases—treating all kinds, merely excluding the following: (1) Pedunculated fibroids partly showing through the cervix; (2) cases in which gangrenous degeneration of fibroid is suspected; (3) fibroids accompanied with carcinoma or those that have undergone sarcomatous degeneration; (4) fibroids which led to acute incarceration of the bladder.

I have found that the Freiburg technique *in toto*, or with some slight modification, has been almost universally adopted by all the gynecological clinics abroad.

Bumm in Berlin, in cases where the fibroma does not reach above the umbilicus, divides the abdomen into twelve fields and also takes six fields in the dorsal and gluteal region. Where the fibroid reaches above the umbilicus he takes six additional fields on the abdomen above the umbilicus. Each field receives about 16 X in each series. He uses only 1 mm. aluminum as a filter—20 cm. focus distance, 9 Bauer with 3½ ma.

He does not give the entire series in one sitting, but divides it into six or eight daily treatments. The series are repeated three weeks after the first treatment. He needs from three to five series to cure his cases, and his latest statistics show 96 per cent. of cures. Has never seen a case of dermatitis develop. In refractory cases he gives in addition 15 m. daily intravaginal raying with each treatment. Wertheim in Vienna divides the abdomen into thirty fields and the dorsum and gluteal regions into sixteen fields. He gives 1000 X for each series—patients are treated for eight hours in one day and whatever is missing from the 1000 X is given per vaginum the next day.

He uses 3 mm. aluminum filter with a focus distance of 17½ cm. for Müller rapid tubes and 13 cm. for Penetrans tubes. Series are repeated at 18-day intervals. This treatment is very much overdone. I found that his results are no better nor quicker than those achieved by other clinics working with one-third of this dosage.

The technique I found at Döderlein's clinic at Munich and at Menge's clinic at Heidelberg are exact copies of that used at Freiburg, so I will waste no time in describing them. Their reported results are also very much alike, that is practically 100 per cent. cures.

The latest technique that I saw carried out in Krönig's clinic at Freiburg is as follows: The apparatus used is a 40-cm. R. G. & S. standing-up coil equipped with a gas and mercury interruptor, the motor of which has a ventilating fan attached to its upper shaft. The coil is built so that there is considerable space between the secondary and the primary, which during usage is kept continually cool by the revolving of the fan attached to the interrupter. This enables the apparatus to be used for a very long time (8 to 10 hours a day) without the primary heating-up too much.

*Read at a meeting of the Mt. Sinai Hospital Clinical Conference, February 5, 1914.

There is a rhythmeur attached to the apparatus which periodically interrupts the current, so that the light instead of being continuous appears in the tube in flashes. This saves the tube from heating up rapidly, and they are only changed at intervals of

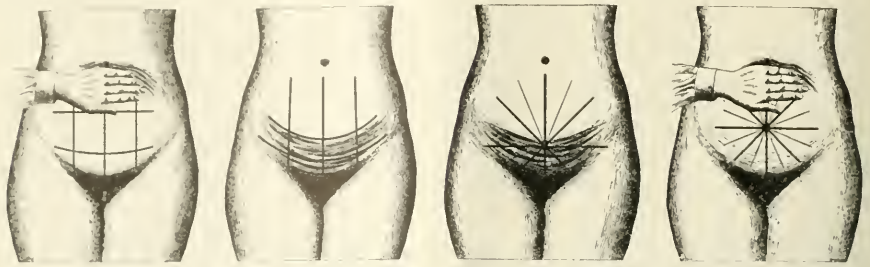

Chart 2 is copied from Gauss's book on Roentgentiefen- therapy, showing how we can get more skin surface for division into fields, by putting the skin on a stretch first up ward and then downward during the division.

about every half-hour. There is a clock arrangement in circuit with the primary, by means of which the time is set for the treatment of each field, so that at the end of the designated period a bell rings and the current is automatically shut off. The size of the condenser depends upon the length of daily use to which the machine is likely to be put.

In circuit with the secondary on the positive side is a 7-cm. spark gap and a Villard valve tube to keep out the inverse current, with an attached oscilloscope to detect it if present. To the negative side is attached a milliameter and a Bauer apparatus to measure the hardness of the tube. The tubes used are of the water-cooled Müller rapid variety, especially pumped for deep treatment, or the Müller penetrans tubes. All equipped with osmoregulators, arranged so that the vacuum can be regulated from the distance without interfering with the working of the tube. An apparatus is used to keep the water circulating continually through the tube during treatment. Focus distance with Müller rapid tubes, 18½ cm. and with penetrans tubes 12 cm. A current of about 4 amp. in the

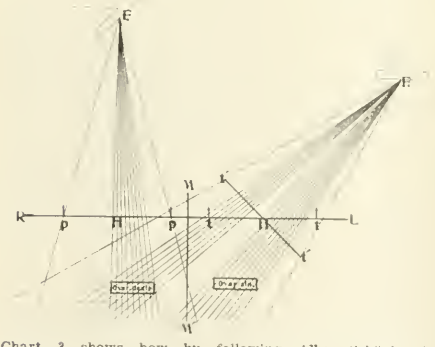

Chart 3 shows how by following Albers-Schönberg's method even by putting the tube and patient in the most favorable position each ovary can receive only two radiations.

primary, 5 ma. in the secondary, and tubes of 8½ Bauer or 13 Wehmelt penetration are used.

The number of ports of entry or fields used, has been changed from time to time. At present the abdomen is divided between the umbilicus and symphysis into twelve fields and the dorsal and gluteal regions into six fields. A 3-mm. aluminum filter is used in every case.

The method of application is as follows: The fields are carefully mapped out with double lines, with skin pencil, the skin surrounding the area treated is covered with two thick heavy lead angles, which are approximated so that only the field to be treated, beginning with the mapped out inner lines is exposed. Over this is placed the Kienböck strips (under a small block of 10 mm. aluminum) to measure the amount of ray given. This is covered with several layers of satrap paper (to filter out the secondary rays) and on top covered with a flat loofa sponge. This is the only part of the patient which is exposed, all the rest being carefully covered with thick lead rubber. The tube stand is now placed over the exposed area, with slight compression. Each field receives about 15 X measured under 13 mm. aluminum.

All fields are treated in rotation in one session, changing the position of the patient and the angle of the tube, to effect as much cross-fire as possible. The duration of an average series is about four hours. Series are repeated at intervals of three weeks. The number of series necessary to effect a cure is from three to six.

No patient is considered cured until she is completely amenorrhoic. Even after she has become so, she receives one or two additional series, so-called consolation series. Their last statistics are 350 cases treated with 100 per cent. cures.

At Döderlein's clinic in Munich I saw two cases of puerperal sepsis treated with *x*-rays. One had 39.8° C. temperature at the time of treatment. Twelve hours later the temperature was 38° C., and twenty-four hours later it was 37° C., where it stayed. The second case was very similar. They had treated fourteen cases up to the time I was there, with very much the same result in thirteen of them. One patient died, but she was practically moribund when she was brought in.

I think this field offers immense possibilities. The result accomplished in these cases is most probably not due to any bactericidal action that the ray may possess, but rather to a change in the blood itself, which makes it untenable to these bacteria. Or it bears out the vaccination theory of the *x*-ray (the rapid manufacturing of the antibodies).

The method of treatment is very similar to that of myoma, but in addition several fields in the thigh are also irradiated. The object is to administer at least 300 X of filtered rays. If the patients are too weak to stand this at one sitting, the dose may be divided into two or more sittings.

At this clinic I saw a set of very convincing charts made by Dr. von Seufert to illustrate the advantage of the many field raying over the Albers-Schönberg method. He kindly permitted me to have them copied and I am glad to be able to show them to you this evening. (See diagrams.)

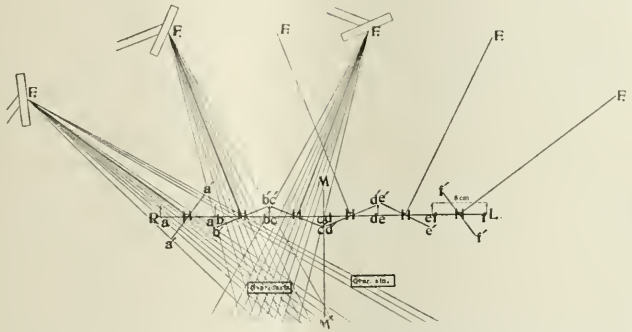

Chart 4 shows how with the many field method, the patient and tube being at the proper angle, at least one ovary can be irradiated through each field, and often both. Thereby multiplying many times the amount of ray we can administer

At de la Camp's clinic in Freiburg, I saw Dr. Küpferle treating pulmonary tuberculosis with *x*-rays. His method is to take a radiograph of every case and divide the affected area into small fields of 25 to 40 sq. cm. Each field receives from 20 to 30 X of filtered rays. Only one field is treated at one time. He has found that these patients do not stand very large doses well. They are very apt to have an attack of hemoptysis if too much ray is given at one time. The treatments are given three times a week and arranged so that each field is irradiated once in three weeks. This is kept up for about three months, when it is discontinued for some time. He had treated fifty patients up to the time of my visit. He thinks that in primary and secondary stages there is decided value to the treatment. In tertiary cases nothing can be accomplished. He also reports very good results in tubercular mediastinal glands and tubercular peritonitis.

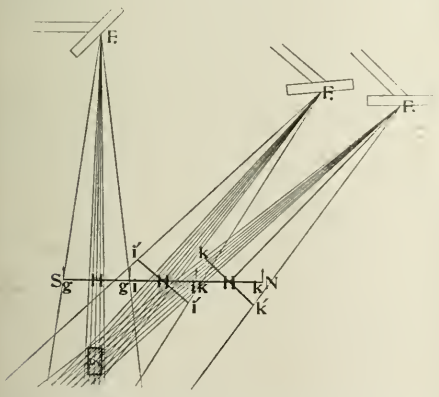

Chart 5 shows how even through the longitudinal area of the fields, by placing tube and patient in a favorable position, at least one ovary can be reached through each field, sometimes both.

At this clinic I also saw a number of Basedows treated with extremely satisfactory results. While I have been treating these cases for a great many years with fairly gratifying results, there is no question in my mind that with the new technique, larger dosage, harder rays, more ports of entry and the 3 mm. aluminum filter we will get better and quicker results than we have in the past. In fact, I think this holds good for all deep-seated conditions amenable to ray treatment.

*Malignant Growths.*—The nonoperative treatment of malignant growths is the absorbing topic of the day. Ever since the Congress at Halle, when men of world-wide reputation announced that in radioactive substances at last we had found an agent which was destined to relegate the surgeon to oblivion in the treatment of these cases, it has become the most widely discussed question in medical science. The tremendous enthusiasm which arose at the time was rather unfortunate, as the world accepted the announcement literally and expectations arose to such a high pitch that reaction was bound to follow.

When I reached Europe in September, I found that the reaction was already setting in, and the extreme wave of enthusiasm displayed at the time of the Congress had decidedly cooled off. They began to realize the limitations of the treatment, and also the fact that the subject was in the experimental stage, and that only years of experimenting could prove its real value. Fortunately this wave of reaction did not have the effect of discouraging further work in this field, but quite the reverse, it acted as a stimulant toward developing mature and serious investigation in every direction.

I found that practically all hospitals and clinics were either already equipped to do work with radioactive substances or were straining every effort toward doing so. In fact the universal cry one hears everywhere is for more mesothorium and more radium. With the inevitable result of the law of supply and demand, the prices are soaring and delivery can be had only after very long delays.

Almost every clinic has its own individual technique of administration. I found the greatest divergence of opinion as to the following: (1) Dosage—This varies between 3,000 and 20,000 mg. hours. (2) Filters—The filters generally in use are lead, silver, gold, platinum, and bronze. (3) Method of protecting the surrounding areas.

They all seem to agree on the following points: (1) Radioactive substances should be used as highly concentrated as possible. (2) They should not cover a large surface but should be kept in as small a

container as will hold them. (The higher the concentration the deeper the penetration.) (3) Less than a certain amount (50 to 100 mg.) should never be used in the treatment of internal carcinoma. (4) Practically no difference can be seen between the action of mesothorium and that of radium. Some think that mesothorium on account of its higher concentration (300 times that of radium) possesses a deeper penetration. Others have expressed the opinion that the action of mesothorium on account of its much more rapid disintegration, is accompanied with more powerful biological action. But this is all theory, and most of the men who work with both assured me that they observed practically no difference in the results accomplished.

My time does not permit me to go into detail as regards the technique of administration used in all the clinics I visited, so I will confine myself to a few of those which have the largest amount of radioactive substances and where most of the work is done.

Bumm in Berlin has 650 mg. of mesothorium divided into 50 mg. capsules. At first he used from 300 to 450 mg. doses, but found that the bladder and rectal tenesmus produced by the application was so serious that he had to diminish his dosage. At present he uses 100 to 150 mg. doses for 10 hours, repeated every second day until they had from 10,000 to 20,000 mg. hours.

The mesothorium is in 1 mm. silver capsules covered with rubber. This is inserted into the cervix, which is covered entirely with a 3-mm. cup-shaped lead stopper, also covered with thick rubber—the rest of the vagina is well packed with gauze to keep this in place. He gets his dermatitis after three or four applications but disregards this entirely and persists with the treatment. Even with the small doses he still gets considerable tenesmus but disregards this also, except when it is very severe.

In connection with this the patients get daily *x*-ray treatments with a high-vacuum tube to different fields and per vaginam through a lead-glass speculum. After a full dose is given treatments are discontinued for about two weeks and then repeated.

Bumm had treated about eighty cases up to the time of my visit. While his immediate results were fairly good, I found that he had lost a great deal of his enthusiasm. Recurrences were beginning to appear, especially in the younger patients. In two cases he had perforations into the intestines, and in two or three other cases bad rectal strictures occurred. The amount of tenesmus produced is still very severe.

I think many of these mishaps were due to the secondary rays from the heavy lead stopper he used. At any rate in the other clinics I visited where lead stoppers were not used, I found decidedly fewer complaints of tenesmus and other accompanying symptoms.

When I visited Latzko, he was just ordering some 3 mm. nickel-plated bronze filters. This is on the principle that secondary rays are produced in metals in direct ratio to their atomic weight, and when two metals are amalgamated the secondary rays produced by the heavier metal are absorbed by the lighter one. He never uses more than 3000 mg. hours followed by 2 or 3 week pause. He thinks that larger doses should be very rarely used.

Döderlein still retains some of his enthusiasm, although he is not quite as positive in his statements now as he was at the Congress. No cancer case has been operated upon at his clinic in the past 2 years. He says that the reason he stopped operating is because some one has to try out mesothorium in all kinds of cases for a long term of years to be able to render judgment in the future as to its real merits. He and Krönig have decided to do so. His latest statistics are as follows: 145 cases treated of which 122 were uterine carcinomas—13 of these died. In 15 cases there is absolutely no objective or subjective symptoms noticeable at this time—10 of these were operable and 5 non-operable cases or recurrences. He has never seen an operable case become worse after mesothorium was used. He has 350 mg. of mesothorium divided into 50 mg. capsules. He uses 100 mg. doses, but this is due to the small amount he has.

Dr. von Seuffert, his chief of clinic, thinks the best technique is to use 200 mg. for 48 hours, repeated in 5 or 6 days for 24 hours or less, then discontinued for 3 weeks. He uses no lead stopper, but merely packs with gauze. He gets some slight tenesmus but not very much. This must be so, because I noticed that while in Bumm's clinic the patients feared the treatment; here they rather like it.

Krönig has 1700 mg. of mesothorium and radium. The stand the Freiburg school takes on the operative interference in carcinoma, as told to me by Gauss is as follows: Where only a very slight operation is required they operate and then ray; where a severe operation would be required, they never operate but only ray. Natives who can be kept under a long supervision are never operated upon, only rayed. Foreigners who can remain only a short time are often operated upon and then rayed. They generally combine the mesothorium with *x*-ray treatments. In deep-seated carcinomas they often dissect back the skin over the area affected, stitch back the flaps, and pour *x*-rays into the tissues *ad libitum*.

The routine they carry out for prophylactic raying after operations is as follows: 1st series, 10 to 14 days after operation; next 3 series at intervals of 4 weeks; the balance of the first year every 6 weeks; the second year, every 8 weeks, and the third year every 3 months.

The area to be irradiated is divided into small fields, and each field is given 15 to 20 X of hard, filtered rays. In carcinoma mammæ we must be sure to take in the sternum. They think that systematic prophylactic treatments with hard filtered rays are of very decided value and should be carried out in every case.

Of 23 cases treated in this way, after the lapse of 1 year 19 are still free—a decidedly better showing than they had in the past.

Czerny and Werner at Heidelberg are doing very good work with their combination of enzytol, mesothorium, and roentgentherapy. They have treated about 6000 cases within the last 10 years. Werner's opinion at present is emphatically that all operable cases should be operated upon as soon as possible and then rayed. He says that the men who stopped operating are going through the same process of enthusiasm that he went through some time ago. He feels sure that time and experience will bring them back to the fold.

The "enzytol" they use is a borate of cholin in combination with colloidal selenium and vanadium. It is given in the form of daily intravenous injections and is always given in combination with Roentgen-ray treatments. It makes the tissues much more susceptible to radioactive treatment.

and in addition has the facility of absorbing the rays and carrying them through the circulation to the metastases.

The injections are given as follows: Begin with 2 c.c. of a 10 per cent. solution to 18 c.c. of a physiological saline solution. This is done for 2 or 3 days, when the dose is increased to 3 c.c. to 17 c.c. of saline solution. Three days later it is increased to 4 c.c. to 16 c.c. of saline solution.

This is continued daily for about 3 weeks or until the patients complain of a great deal of weakness. It is then discontinued for 3 weeks and repeated again. Injections must be given very slowly. During the injections the patients suddenly develop symptoms of congestion, salivation, lacrymation, and nausea, but this only lasts from one-half to one minute. In carcinoma of the bladder the enzytol is injected through a catheter, 10 c.c. of a 10 per cent. solution to 50 c.c. of saline.

If veins cannot be found for intravenous injections, the solution may be injected into the gluteal muscles. For this purpose they use 4 to 5 c.c. of the 10 per cent. solution undiluted. In prophylactic treatments after operations, they also combine enzytol injections with Roentgen ray.

Menge has also stopped operating, but as he explains purely in an experimental way. His technique is to insert 50 mg. in a 1 mm. gold filter, covered with about 2 mm. rubber and gauze into the cervix, and to place 50 mg. on each side of the abdomen. This is left in place for about 72 hours. Treatments are repeated at intervals of 3 weeks. He advises against the use of dermatol gauze as it produces secondary rays—plain sterilized gauze is the best.

I shall not attempt to go into the question of the technique used by other clinics I visited, because with slight modifications it would only be a repetition of what I have already described.

In conclusion I wish to say that if I were asked to summarize briefly the result of my observations during this short trip on the question of the present status of the non-operative treatments of malignant growths, I would do so as follows:—

1. The extreme enthusiasm displayed by the men at the Congress at Halle was entirely too previous, and while unquestionably very remarkable results are accomplished with radioactive substances in the treatment of cancer, the matter is purely in the experimental stage.

2. Even in the short time elapsed since the Congress, the extreme optimism has cooled off considerably and the men who made positive statements then are becoming much more guarded.

3. The question of proper dosage, filters, and other technique is a very complicated one which only years of work will solve.

4. The treatment with radioactive substances has shown sufficient results to justify the surgeon in discontinuing operations in cases of surface carcinoma and that of the mucous membranes easily reached, in patients who can be kept under long and continuous observation, but in no other class of cases. In other cases, operative interference, followed by prophylactic raying, carried out systematically for years is still the best method of treatment.

5. There is practically no difference noticeable between the action of mesothorium and that of radium—with the possible exception already mentioned.

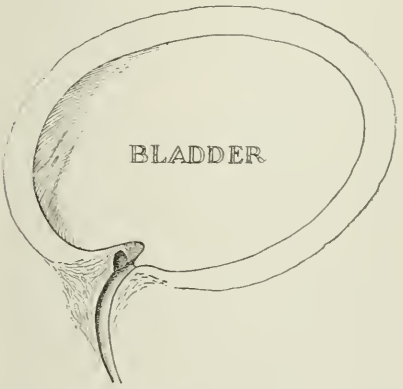
## CICATRIX OF BLADDER RELIEVED BY FULGURATION.*

By L. Bolton Bangs, M.D.,
New York.

Three cases of an obstructive fold at the neck of the bladder, following prostatectomy, have come under my observation, two of these in my own practice. One was relieved by incision of the fold by means of perineal urethrotomy, one refused this treatment, preferring to go on, as he was in moderate comfort, and the third is the subject of this report.

The history, in brief, is that of a man, aged fifty-two, who was brought to me by a doctor from another State in December, 1913, and who about three years ago had begun to have frequency of urination, together with the symptoms of obstruction to the stream of urine. These evidences of prostatic enlargement persisting and becoming more notable, in May, 1913, his doctor performed a suprapubic prostatectomy. The doctor says that the prostate was only moderately enlarged, but that the capsule was very much thickened. The wound healed slowly and a urinary fistule persisted almost



to the present time; that is to say, for over five months urine escaped above the pubes. At no time since the operation has he been able to void his urine without a sense of obstruction, which has gradually increased in intensity. Although he is up at night to urinate but once, during the day he is obliged to urinate every two hours, always with great hesitancy, sometimes with urgency, and the stream is small, weak, and dribbling. In attempting to relieve this difficulty his surgeon has passed into the bladder a steel sound of size No. 30 F.; but no soft catheter or small instrument could be entered. For a time he was able to void his urine easier when lying down. There has been pain only when the bladder was distended and urination was attempted. At the time of my first examination he voided with a dribbling stream hazy, turbid urine. A natural-curve, gum-elastic catheter entered easily and 5 ozs. of purulent residual urine was obtained. On attempting to introduce the cystourethroscope its beak was obstructed, and it finally was entered by withdrawing it slightly and after marked depression of the ocular end. Both ureteral orifices are normal and the bladder is moderately trabecu-

*Read at the 260th meeting of the Practitioners' Society, February 6, 1914.

lated. Just within the internal orifice of the urethra, and apparently at the site of the prostatectomy is a dull white transverse cicatricial fold with bulging lateral processes. Anterior to and beneath this fold, in the median line, is a pocket into which the tip of straight instruments will easily enter and be arrested. The verumontanum is seen anteriorly, and is apparently normal. The question of how to relieve the patient's dysuria was discussed with his doctor, and I advised him to place the man in proper circumstances for a general anesthetic, open the perineum, and freely divide this cicatricial fold. To this the patient demurred, saying that as he had been so long confined to his house and away from his business, he deprecated such a procedure, and asked if there was no other method that would promise relief. I then suggested the possibilities of fulguration, stating that he would not be laid up nor detained from his business, and that the operation could be done with local anesthesia. For this purpose he was placed under my care, his doctor not having the facilities. The operation was performed four times, at intervals of a week. After the second time he experienced relief to his frequency and sense of obstruction, and subsequently he could hold his urine at will. To use his own language: "I do not have to run to the urinal every hour or so." There was gradual diminution in the residual urine, which at first having been 5 ozs. (150 c. c.) was only 6 drams at his last visit to me, on January 9. The accompanying illustration represents, diagrammatically, the conditions as revealed by cystoscopy and the results of the fulguration. A wide groove has been made in the median line of the fold, the anterior end of the groove being directed toward the sulcus, or cavity beneath the fold. An interesting observation in this case was the contrast in the reaction of the tissue of this dense, waxy-white cicatrix to that usually seen in tissues of the enlarged prostate. In the cases of enlarged prostate which I have seen the line of tissue acted upon by the spark is almost immediately covered by a delicate white pellicle, and on either side of this pellicle will be seen a narrow margin of bright red hyperemia, with some of the vessels distinctly outlined. But in the cicatricial tissues in the case reported, although the effect of the cauterization could be distinctly noted in a dense white eschar, the hyperemia on either side of this eschar was barely noticeable.

## AUTOSERUM INJECTIONS IN CERTAIN OBSTINATE DERMATOSES.*

By WILLIAM S. GOTTHEIL, M.D.,

NEW YORK.

PROF. DERMATOLOGY, FORDHAM MEDICAL SCHOOL; DERMATOLOGIST, CITY HOSPITAL, ETC.,

AND

DAVID L. SATENSTEIN, M.D.,

NEW YORK.

ASSISTANT DERMATOLOGIST, CITY HOSPITAL.

THIS is a preliminary report of the results attained from a method of treatment that has not as yet been employed here in some obstinate and common general dermatoses. It is no exaggeration to say that inveterate psoriasis, generalized eczema, and chronic urticaria are not infrequently the despair of the practitioner. In many cases treatment along accepted lines gives unsatisfactory results. Here is a typical case: General eczema of seborrheal type for four years, at times retrogressing so that only head, face, and genitals were affected, at other times spreading over the entire body surface; all manner of internal, dietetic, and external treatment at competent hands with only partial and temporary effect; seven months' treatment as an in-patient in a special hospital; condition entirely unimproved.

During the past year Linser, Ulmann, Heuck, Spiethoff, and others, have employed serum injections in the affections above mentioned, and also in purpura, prurigo, pemphigus, and dermatitis herpetiformis, and have reported remarkable results. We shall not attempt the rather hopeless task, in the present state of our knowledge and experience, of explaining the action of the procedure. Blood serum, whether autogenous or foreign, whether active or deactivated, undergoes very important changes after it has been withdrawn from the body; the material reintroduced into the veins is not the same that has been withdrawn from it. Administration of serum apparently diminishes the sensitiveness of the skin, so that there is less tendency to persistence and spread of the local symptoms, and ordinary medication is more effective and can be pushed without exciting reactive inflammatory phenomena. There is reason to think that the effects of the serum administration are further reaching than this; but this must be left for further investigation to determine.

In the wards of the City Hospital here we have unrivaled opportunities for careful experimentation with the class of cases in which the new treatment might be useful. The press of work on the house staff and the laboratory was such, however, that it was late in the fall before it was well under way. We therefore have at our disposal the records of twelve cases only, six of very extensive general psoriasis, three of generalized eczema, two of pemphigus, and one of leprosy. Several more cases are under the new treatment at the present time.

As we had no guide as to dosage, frequency of administration of the serum, etc., our methods were purely empirical, and were determined largely by the possibilities in the busy hospital wards. The psoriasis and eczema cases received autogenous serum; the pemphigus and leprosy cases that of relatives and that of a case of dermatolysis when it was available. The injections were given once a week, three to four intravenous administrations of from 20 to 30 c.c. being administered in the psoriases and eczemas before local treatment was begun, making about 100 c.c. in all; in the pemphigus and leprosy cases they were continued longer. The serum was not deactivated, being administered two or three hours after it was drawn. We are therefore unable to say that either the dosage or the intervals indicated are the best; possibly larger single doses at more frequent intervals will be found better. It was evidently unnecessary, save as a matter of convenience, to keep the psoriasis and eczema patients in the hospital while they were getting the injections; they were receiving practically no local treatment, or only such as had been ineffectively used for long periods before; and they might have been at home during this time. This would mean a reduction of the period of hospital detention by at least 75 per cent.

CASE I.—Julia F., twenty-one. General psoriasis for the last eight years, three to four attacks yearly at first, now continuously present. Has been here for it; eight weeks' time, with chrysarobin up to 40 per cent.,

*Read at a meeting of the New York Physicians' Association, February 26, 1914.

and arsenic required to clear her skin. Present attack began six months ago. Improvement of the lesions during the serum injection period, without any local treatment at all. January 24, chrysarobin-vaselin 3 per cent. to body, white precipitate ointment to scalp. January 26, lesions disappearing rapidly. January 27, chrysarobin 5 per cent. January 31, lesions all gone. Time of local treatment, 6 days.

Case II.—John H., forty-six. Has had psoriasis for the last twenty-five years; has been in the hospital twice during the last five years for it, staying six to eight weeks each time, and getting chrysarobin up to 40 per cent. and arsenic in full doses. Present attack began two months ago. Large, greatly thickened patches, considerable itching. Improvement in the lesions, lessened scaling and itching during the serum treatment. January 2, chrysarobin 3 per cent. January 3, improving rapidly, chrysarobin 5 per cent. January 5, lesions gone. Time of local treatment, 3 days.

Case II.—Archibald MacP., 39, has had psoriasis 5 years; was in the hospital for 6 weeks for it two years ago; present attack has lasted 18 months; self medication. Disappearance of the scaling during the serum injections. January 20, chrysarobin 5 per cent. January 24, marked improvement; lesions smooth and flat with the general skin surface. February 4, eruption all gone, save a few lesions on legs. Time of treatment 15 days; result imperfect possibly because the serum injections were administered at intervals of two or three days, instead of a week. A similar observation has been made by a German writer.

Case IV.—Hannah MacC., 40, psoriasis for 15 years, one attack at least each year. Was in the hospital 5 years ago, receiving chrysarobin up to 30 per cent. Has present eruption about 4 months; many greatly thickened plaques. Serum pushed in this case to over 100 c.c., because after a primary improvement new psoriatic lesions began to appear while it was being given. January 7, chrysarobin 3 per cent. to body, white precipitate ointment to scalp. January 9, great improvement; lesions fading rapidly; on the arms, purposely left without local treatment, the same occurred. January 10, lesions gone. Time of treatment, 3 days.

Case V.—James McG., 28, has had a number of attacks of generalized psoriasis since his 18th year. Acute outbreak. Marked improvement under the serum. January 15, chrysarobin 3 per cent. January 20, lesions gone. Time of treatment, 5 days.

Case VI.—Joseph D., 30, had been in the medical ward for an acute nephritis since July; on recovery sent to the dermatological ward for his psoriasis, which he has had for years. Two years ago was here 6 weeks for it. No change, other than decrease in the thickness of the plaques during the serum administration. January 15, chrysarobin 3 per cent. January 17, slight improvement, chrysarobin 5 per cent. January 22, lesions all gone. Time of local treatment, 8 days.

Case VII.—James R., 40, eczema rubrum, legs and arms, 6 months duration. Had been in Bellevue Hospital, no improvement. There was considerable betterment under the serum alone, especially in the acuity of the inflammation, and the itching; the local treatment being a plain oil dressing. January 20, 10 per cent. ichthyol and 10 per cent. zinc oxide ointment. January 30, arms and hands almost well; legs much better. Time of local treatment 10 days, in an eczema of 6 months' standing, with very great improvement.

Case VIII.—Ida G., 18, extensive general seborrheal eczema following an attack of erythma multiforme. Had been bedridden in a hospital for many months, under the most varied general and local treatment, without any result. Serum from sister, 120 c.c. up to the present. She improved markedly under the same treatment that she had been getting before (2 per cent. salicylic oil), especially as regards her legs. December 22, a new general eczematous outbreak, papular in character. January 6, attack recovered from; slow but distinct improvement under the same treatment.

Case IX.—Rose S., 18, had had a general eczema for 5 years past, improving at times, but never getting well; practically unchanged for 9 months past. Prolonged hospital and other treatment. Serum treatment began Jan. 18. Marked improvement under boric acid ointment with 2 per cent. sulphur. Case unconcluded.

Case X.—Sarah G., 40, pemphigus foliaceus. Though patient was in a very advanced stage of the affection, the entire inefficiency of all other treatment led us to put her on the serum. She received but two injections, which did not seem to have any influence on her condition; she died two weeks later.

Case XI.—Michael S., 42, pemphigus vegetans. This was also an advanced case which was getting from bad to worse in spite of all our efforts. He received 3 injections of serum from a case of dermatolysis in the wards; there was some improvement in the local symptoms, but a fatal termination was not prevented.

Case XII.—Lena T., aged 40; maculotubercular leprosy, ulcerations of the phalangeal joints, lepromata of the vocal cords, etc. This patient has been receiving weekly serum injections of serum from a brother and sister, and with marked and steady improvement. She has gained in weight and strength, her ulcerations are very much better, and her laryngeal symptoms are much less distressing. The general improvement is so apparent that there is no difficulty in getting a steady supply of serum from the relatives above mentioned.

The apparent results from the serum treatment were most noticeable in the psoriasis cases, in all six, on which it apparently had a marked influence on the reactivity and susceptibility of the skin. They were kept in the hospital during the time of the injections for convenience of observation only; no local treatment was used during that time. They might as well have been at home. The times of local treatment were six, three, fifteen, three, five, and eight days, respectively, about six days on the average. This is to be compared with the six weeks or more of local treatment that is usually required. It means about one week's hospital treatment of these obstinate and recurrent cases instead of six, a point of prime importance economically, as well as from the patient's viewpoint. In no case did we have to exceed 5 per cent. of chrysarobin strength to clear the skin rapidly, which must be compared with the 30 and 40 per cent. formerly required. Finally, no case received any internal treatment at all. Those patients who had been in the hospital in former attacks, and who were therefore in a position to compare results, were the most enthusiastic in their appreciation of the new method.

The eczemas were fewer in number, since naturally only the most extensive and obstinate cases are kept in the hospital. The results were less decisive than those in the psoriases, yet great improvement was noted in all, and we feel hopeful that further experimentation will substantiate the value of the serum treatment in these cases.

In the two cases of pemphigus there were practically no results at all, though most wonderful records have been published in Germany in precisely this disease. Both cases, however, were practically hopeless at the time that the treatment was instituted. Its use was the counsel of despair, and we felt sure that it could do no harm. It may be of value in earlier cases, and any course of treatment that gives the least hope in these cases deserves further trial.

Finally, in the case of leprosy the benefit from the treatment was unmistakable and quite rapid. There is no reason to hope that it will do more than ameliorate the symptoms and improve the patient's general condition; but, as is the case with pemphigus, even that is worth striving for in a malady that is so thoroughly beyond the reach of all our ordinary therapeutic methods.

We make this preliminary report with the conviction that as an aid in the treatment of some very obstinate and serious dermatoses, and possibly as more than that, the serum treatment is deserving of further careful trial and experimentation. We also desire to acknowledge our indebtedness to the Pathological Department of the hospital and to thank Dr. Larkin and the staff for their aid and interest in the work.

## PSYCHIATRY AND CERTAIN MILITARY PROBLEMS.

THE importance of psychiatry in medicine is beginning to be recognized and in consequence its study is being promoted in all medical schools. In most modern hospitals opportunities are provided for the clinical study of psychiatry, for it is felt that in these days when degeneracy appears to be rife it is essential that as much as is possible should be learned of the subject. In a lecture delivered at the summer conference, 1913, of the U. S. Naval War College, by Dr. W. A. White, it was pointed out that psychiatry and the military medical service were intimately related, that is, psychiatry was of great importance to the military service, in so far as by its means the enlistment of defectives might be prevented to a very large extent. White is of the opinion that it is a popular delusion that the ne'er-do-well, the black sheep of the family, will be picked up and made a man of by the discipline of military life. According to his views quite the contrary is the case. The ne'er-do-well is so because he lacks the ability of continuous application, and when he is subjected to the rigid discipline of the military organization, he of necessity endeavors to slip from under the weight of his responsibilities and duties and thus begins that series of minor infractions of military regulation which frequently ends so disastrously.

Mental breakdowns are very apt to occur in war time, and if the subject has certain latent tendencies they will be brought to light by the stress and exigencies of war conditions. For instance, it has been demonstrated that in such circumstances there is an increase in the number of alcoholic psychoses, an increase in the number of psychoses due to syphilis, and an increase in the psychosis of metasyphilitic paresis. Persons with these tendencies are more prone to break down in war time than in the time of peace, and therefore are not fitted to be soldiers. A knowledge of psychiatry would come in good stead to eliminate these unfit from the military standpoint. That an individual with an alcoholic psychosis is not fitted for a soldier's life, at any rate, in war time, is self evident, but White shows from the experience gained in the Russo-Japanese war that the syphilitic psychosis is likewise of the first importance. At the Russian Psychiatric Hospital at Harbin, during the war, the percentage of paresis among those brought back from the front was 5.6. Undoubtedly its development was hastened by war conditions and this clearly shows the influence of these conditions upon those who have syphilis.

After discussing temperamental fitness and character the author comes to eugenics and thinks that it would be interesting to construct family charts to see what are the hereditary probabilities in different individuals. Such charts might be considered at the time of admission to the Naval Academy, and if out of a number of applicants there were in a certain proportion marked hereditary tendencies which might very well come to expression in the particular individual under consideration, perhaps it would be better to put him aside for one with a clearer family record.

In concluding the paper some suggestions were made. In the first place data which are being collected might perhaps present some evidence to a person psychologically trained that they would not present to a person without that training. A psychological analysis of some of the great generals is possible from the literature that exists regarding them. Field work, too, in psychology is possible; and lastly White suggests the readjustment of the service so that men will come into positions of command well before the arteriosclerotic period and the elimination from promotion to higher grades of alcoholics and syphilitics.

## COMMON ERRORS IN THE DIAGNOSIS OF INFECTIOUS DISEASES.

THAT 8 per cent. of the total number of admissions to the contagious disease hospitals of London during the year 1912 should have been incorrectly diagnosed by the physicians who had sent these cases to the hospitals, indicates that many difficulties beset the diagnosis of this class of cases. This frequency of error is all the more distressing in view of the fact that a patient referred to an infectious disease hospital, if not suffering from an infectious disease is likely soon to develop one. In New York the possibility of such an occurrence is minimized by the fact that, as a rule, before a patient is admitted to a contagious disease hospital an expert diagnostician is sent to pass upon the diagnosis made by the original medical attendant.

The subject of errors in the diagnosis of this group of cases is discussed by E. W. Goodall in the *Clinical Journal*, December 24, 1913. He naturally points out that the proportion of errors is altogether too high. He shows that during 1912 in London there were one hundred different diseases which were mistaken for the five common acute infections, namely scarlet fever, diphtheria, measles, typhoid fever, and whooping cough. The causes of error are the difficulties due to the surroundings of the patient, the necessity of arriving at a diagnosis on probabilities in order that the patient may be removed as early as possible to the hospital, inexperience and ignorance, carelessness, faulty methods of examination, and inherent difficulties in diagnosis. Not a few errors are due to the survival of certain outworn beliefs. Thus many prac-

titioners even at the present day regard a scarlatiniform rash as an indication that scarlet fever is present, forgetting that such a rash may be a prodromal eruption in measles, chickenpox, or smallpox. It may be the rash that occurs in rubella and occasionally in measles; it may be the result of the administration of belladonna or quinine; or it may be the result of an enema. A recurrent scarlatiniform erythema occurs in certain skin diseases. The morbilliform rash characteristic of measles occurs as an initial or prodromal rash in smallpox, as a secondary rash in scarlet fever, diphtheria, measles, typhoid fever, and other infectious diseases including acute rheumatism. It may be a drug rash, *e.g.* the copaiba eruption, or an antitoxin rash. It may be the result of an enema or it may accompany any septic condition. The morbilliform rash also occurs in erythema multiforme.

The strawberry tongue is not pathognomonic of scarlet fever. It occurs in measles, diphtheria, and septic sore throat, and it may be an accompanying manifestation of any case of erythema. Furthermore, desquamation is not necessarily confined to scarlet fever and conversely there are certain cases of scarlet fever that are not followed by desquamation. Desquamation resembling that following scarlet fever may also occur after measles or rubella, or after a serum eruption or a septic rash. It may occur even when there has been no rash at all and also in typhoid fever and acute rheumatism. German measles is often mistaken for scarlet fever. In the majority of cases of this affection the eruption comes out on the face in the form of small pink discrete spots. If these spots on the face are seen scarlet fever is absolutely excluded. The spots soon come out on the trunk and then disappear from the face and the eruption on the trunk is replaced by a diffuse erythema. This, according to Goodall, is the difficult stage of diagnosis in rubella, for if the spots on the face have not previously been seen it is impossible to state whether the case is one of scarlet fever or one of rubella. It is impossible at times to avoid confusing rubella with very mild scarlet fever.

## ACCOUCHEMENT BY HYSTERECTOMY, WITHOUT PRELIMINARY OPENING OF THE UTERUS.

Under this title Casalis and Lecocq (*Ann. de gynéc. et d'obst.*, February, 1914) quote one case already published by Reymond and report two others in which this operation was performed, and comment upon the advisability of its employment in suitable cases. In Reymond's first case there was placenta prævia, all efforts to detach this and push it aside in order to reach and rupture the membranes had proved futile, the woman had lost a great deal of blood and was in desperate condition. She was hardly able to speak, the extremities were cold, the pulse was uncountable, and the patient continued to lose blood in great abundance. Hysterectomy without the preliminary extraction of the child was accordingly performed immediately, the work being so planned that the uterus was removed within one minute after the second uterine artery was clamped. The uterus was taken away from the operative field, immediately opened by an assistant, and while Reymond was placing the first ligature on a vascular pedicle he heard the cries of the infant. The second patient, operated upon by Reymond and Casalis in July, 1912, had epithelioma of the cervix. Here the uterus was removed 10 seconds after the second uterine artery was clamped, 20 seconds later the child was taken from the cavity of the uterus and immediately cried. The third patient was operated upon by Casalis and Lecocq in September, 1913. She had a contracted pelvis and her first four children, all breech presentations, had died before delivery could be completed, due to the difficulty in extraction of the head. The fifth was also a breech presentation, but in this case the child was delivered alive after a very difficult labor. In this, the sixth pregnancy, the woman was in labor on admission to the hospital and the conditions as stated by the authors was as follows: "Arrest of labor after complete dilatation; membranes ruptured; uterus commencing tetanic contractions; child living; pelvis contracted." Fearing rupture of the uterus if these contractions were allowed to go on, operation was undertaken. An incision was made, starting four finger breadths below the xiphoid appendage and descending almost to the pubes, and the uterus was brought out through the wound. The round and broad ligaments were ligated and divided. Section of the vagina was made below the fetal head, and then the uterus was rapidly removed and opened by an assistant. He removed a child weighing 3,870 grams (about 8½ pounds) who cried almost immediately. After restoration of the pelvic floor, as in a normal hysterectomy, an appendicectomy was performed. In all these cases the mothers and children did well and no post-operative complications are reported.

The authors state that the indications for this operation are those of the Porro operation. But hysterectomy without preliminary opening of the uterus not only has all the advantages of the Porro but it also offers greater security. No more infection is to be feared, since the uterus is opened far from the operative field. In cases of cancer of the cervix one has much less risk of recurrence since the mass is removed *en bloc*. There is no hemorrhage to fear since the pedicles are tied or clamped one by one before the removal of the uterus. The greater rapidity of the intervention and the uneventful post-operative course are some of the arguments which militate in favor of this technique. In closing the authors remark: "One sees that the intervention which we propose is simply hysterectomy without preliminary opening of the uterus. The uterus, having been removed as if the case were one of voluminous fibroid, is then opened by an assistant. * * * One sees that the mother would have every benefit to be derived from that (Porro) operation. As for the infant, if it is living at the beginning of the intervention it *ought* to be alive when taken from the uterus—our three observations establish faith in that. Besides, in the cases of cesarean section after death of the mother there are some where the infant has sur-

vived some time, and if he has succumbed, it is because the death of the mother is generally preceded by a period of asphyxia during which the fetus is equally asphyxiated. In the cases of prolapse of the cord, the placento-fetal circulation is often interrupted for a considerable period of time and the fetus does not succumb unless the compression is marked and prolonged."

The authors' conclusions certainly seem justified by the happy outcome of these three cases, and the reasoning is logical. Since the fetal circulation is not shut off until the second uterine artery is clamped, and this is left until but a few snips of the scissors remain necessary for the removal of the uterus, there is no apparent reason why a live child should not be found after the few seconds' delay in removing and opening the uterus at a safe distance from the operative field. The successful outcome of the operation naturally presupposes a competent operator who is capable of rapid work after the second uterine artery is clamped, and that, too, without inflicting injury to the bladder or rectum. In the comparatively rare cases where the Porro or some modification of that operation might be indicated, it would seem *a priori* that this should be the operation of choice. It will be interesting to note the attitude adopted by American gynecologists and obstetricians toward this procedure.

### The Metabolism in Epilepsy.

The discovery of oxyprotein acids in the normal urine by Bondzynsky and his collaborators and pupils, and the inference that these acids are found in an increased amount in the urine of persons who have marked disturbances of metabolism, stimulated inquiry along this line by S. Kozlowski, with special reference to epileptics. His results are reported in the *Zeitschrift für klinische Medizin*, Vol. 79, Nos. 3 and 4. He found thata oxyprotein acids are in some cases of epilepsy excreted in enormous amounts. At the same time, there is an accompanying increase in the formation of ammonia in the organism. Possibly these chemical changes are more or less directly related to the epileptic attacks. This supposition is strengthened by the fact that epileptic attacks are diminished if meat is withdrawn from the diet and replaced by milk, for this diet diminishes the formation of oxyprotein acids not only in epileptics but also in healthy people. In agreement with these facts one may cite the observation made by Krainski that lithium carbonate as well as borax diminishes the frequency of epileptic seizures. These salts lead to the formation of fixed bases, which combine with the oxyprotein acids. The question now arises whether the periodicity of epileptic attacks can be explained on the supposition of a chemical intoxication of the body. According to the author, it appears that the periodic onset in these attacks can be easily explained on this basis, for it must be considered that in the body of the epileptic the toxic substances in unfolding their activity find a suitable soil in the periodically increased irritability of the nerve centers.

### Metastatic Costochondral Necrosis.

Not many years ago all suppurative necrotic lesions at or near the junction of the ribs with the costal cartilages would have been regarded as tuberculous in character. Then came the "typhoid rib," the nature of which proved very obscure at first, but was finally regarded as an osteoperiostitis implicating the integrity of the cartilage. The same lesions were next seen after influenza, and it has now become certain that nearly every infectious disease may be followed by prompt metastases in this locality. At a recent meeting of the Berlin Surgical Society (*Berliner klinische Wochenschrift*, February 16) Harzbecker reported 10 miscellaneous cases from Körte's clinic. The lesions followed immediately upon articular rheumatism, bronchitis, typhoid fever, and appendix-peritonitis. Pain and circumscribed swelling were followed by abscess formation and dead cartilage could be felt after suppuration had occurred. In the appendix-peritonitis case the *B. coli* could be recovered from the pus of the abscess. The perichondrium had become detached from the cartilage. There is but one method of treatment, viz., extirpation of the cartilage which is necrotic throughout. Axhausen smoothes the free ends left behind and interposes some form of the soft tissues. Repeated operation may be required for postoperative fistulæ, chiefly in old subjects.

## News of the Week.

**Public Health Service Examination.**—On Monday, April 27, 1914, examinations of candidates for admission to the grade of assistant surgeon in the United States Public Health Service will be held Candidates must be between twenty-three and thirty-two years of age, graduates of a reputable medical college, of good moral character, and with one year's hospital or two year's professional experience. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order. They will receive early appointments. Assistant surgeons receive $2,000 a year, and after four years' service are entitled to examination for promotion to the grade of passed assistant surgeon. For invitation to appear before the board of examiners, application should be made to the Surgeon-General, Public Health Service, Washington. D. C.

**Hospital Investigation Report.**—The Board of Estimate of New York recently received a report from the Hospital Investigating Committee appointed some time ago to look into the conditions of the city hospitals. This report, which is based on a three months' study, severely criticises conditions at Bellevue and the Kings County Hospital, Brooklyn, in particular. It also criticises other hospitals in the city for the transfer of patients in a dying condition to Bellevue, and intimates that this is done in order to keep down the death rate of the private hospitals. It finds that at Bellevue patients with uninteresting ailments are sometimes prematurely discharged in order to make room for other cases of more interest to students; that the large percentage of incorrect diagnoses at Bellevue is partly due to lack of medical knowledge (in general, not of the medical staff in particular) and partly to hasty and insufficient examinations and too much reliance on inexperienced house physicians and internes; and that the autopsy service at Bellevue is poor because the law is so interpreted that nearly all unclaimed bodies must be sent to the medical colleges. It criticises the waste of hospital space, in

that there is apparently no attempt to transfer patients from overcrowded surgical wards to vacant beds in the medical wards, and points out that the new and splendidly equipped morgue in the Bellevue Pathological Building lies idle because the hospital authorities and the Charities Department are unable to agree on its operation. There is an intimation in the report that Bellevue is operated with emphasis on the needs of the medical schools rather than on hospital efficiency —which the committee, in its inexperience, apparently considers to be incompatible.

**Plague in Havana.**—One death from bubonic plague was reported from Havana on March 26. This is the first death that has occurred, and no new cases have been reported. The Public Health Service is preparing to enforce rigorous quarantine regulations for passengers and freight from Havana for the United States.

**Meningitis on Steamship.**—The North German Lloyd steamer *Berlin* which arrived at Naples on March 25 from New York, was held at quarantine because of the presence of meningitis among the steerage passengers. The *Berlin*, which left here on March 14, carried several steerage passengers who were ordered deported from this port, and it is probable that the disease originated among them.

**Aviation Deaths.**—In a speech before the Aviation Club of London on March 20, Lord Lonsdale said that 407 aviators had been killed in various countries since 1910, and he ascribed this enormous mortality in large measure to the excessive use of alcohol.

**River Bathing to Stop.**—Health Commissioner Goldwater of New York has announced that the Health Department will not permit bathing in the Hudson, East, or Harlem Rivers about New York during the coming summer. No permits will be issued to keepers of bath houses along the water front. This action is made necessary by the foul condition of the water because of the enormous amount of sewage discharged into the rivers.

**Measles at Cornell.**—An epidemic of German measles among the students at Cornell University, Ithaca, has filled the University Infirmary. Twenty-five cases of the disease are being treated there, and a number of other cases are scattered about the town.

**General Gorgas Honored.**—Oxford University, at a special convocation on March 24, conferred the degree of Doctor of Science honoris causa on Surgeon-General Gorgas of the United States Army, who recently returned from South Africa.

**Death Rate Higher.**—The mortality rate in New York City for the week ending March 21, was 16.42 per 1,000 of population, an increase of 0.49 over the previous week and of 0.06 over the corresponding period of 1913. The actual number of deaths was 1,757. The death rate for the first twelve weeks of 1914 was 14.85 per 1,000 of population, or 0.29 less than for the same period of 1913.

**New Sanitary Superintendent.**—Dr. Haven Emerson of New York has been selected by Commissioner Goldwater for the office of sanitary superintendent in the Department of Health, a position which has been vacant since the retirement of Dr. Walter Bensel last October. Dr. Emerson is at present an associate in physiology and medicine in Columbia University, from which institution he was graduated in 1899.

**Dr. Henry Maule Crookshank**, ex-British Controller of the Public Debt of Egypt, who was a Fellow of the Royal College of Surgeons of Edinburgh and a member of the Royal College of Surgeons of England, died at Monte Carlo on March 25, aged 65 years.

**State Legislation.**—In the closing days of the just completed session of the New York State Legislature action was taken on several bills of interest to the medical profession. The McClellandThorn bill, backed by the Christian Scientists and previously passed by the Assembly, was, after a sharp fight, also passed by the Senate by a vote of 79 to 50. Its passage ends the fight for recognition waged by the Christian Scientists for many years, provided, of course, that the bill is approved by the Governor. One of its supporters is quoted as saying that the passage of the bill "has enabled New York to take her rightful place among other progressive States in protecting by statute the medical rights as well as the religious rights of their citizens." The bill licensing the socalled naturopaths, which was passed by the Senate, was killed in the Assembly. The Blauvelt bill, regulating the sale of bichloride of mercury, was beaten in the Senate by a vote of 18 to 16. This bill provided that bichloride of mercury should be sold only on a physician's prescription, and that the tablets should be coffin shaped, colored green, and put up in triangular shaped bottles also colored green. The bill to recognize and legalize the practise of chiropractic was also defeated in the Assembly. The Adler cold storage bill, prohibiting the storage of foods apparently impure and making it a misdemeanor for a person or company to offer impure food for storage, was passed by both the Senate and the Assembly. Other bills which passed both houses and are now before the Governor are: the Boylan bill, prohibiting the sale of habit-forming drugs without a physician's prescription. The Herrick-Conkling bill, legalizing the practice of surgery by osteopaths. The Godfrey bill, prohibiting the sale of misbranded or adulterated foods. The Frawley bill, making it a felony instead of a misdemeanor to sell or possess cocaine in violation of the law.

**State Vital Statistics.**—The Bulletin of the New York State Department of Health gives the total number of deaths throughout the Sate during the month of January as 13,353 or 1,953 above the average for the past fifteen years. The deaths of persons over sixty years of age formed 36 per cent. of the total and numbered 400 more than the average; while those of infants under one year of age formed only 14 per cent. and were 300 less than the average. The births during the month totaled 19,367 or 6,014 in excess of the deaths. With the exception of Albany and Troy, all of the first-class cities in the State shared in this excess of births over deaths. In Albany, however, the deaths exceeded the births by 44, and in Troy by 69.

**Gifts to Charities.**—The Massachusetts General Hospital, Boston, receives $50,000 from the estate of the late Mr. Nathaniel Thayer, one of the trustees of the hospital, and the Boston Lying-In Hospital receives $10,000, and the Clinton Hospital, Lancaster, $5,000 from the same estate.

**A Farewell Reception to Dr. Elise S. L'Esperance**, this year's winner of the Mary Putnam Jacobi Fellowship, will be given on the afternoon of April 4, 1914, at the residence of Dr. Emily Dun-

ning Barringer, 828 West End avenue, New York City. The women physicians are invited to meet Dr. L'Esperance and also Dr. Alice Rohdé, the first winner of the fellowship. The Mary Putnam Jacobi Fellowship is open to women graduates in medicine, the fund having been raised through the efforts of the members of the Women's Medical Association of New York City, many of whom were pupils of Dr. Jacobi at the Women's Medical College of the New York Infirmary for Women and Children.

**VII^e Congres international d'Electrologie et de Radiologie medicales.**—This congress, the first session of which was held in Paris in 1900, will meet this year at Lyon, France, on July 27 to 31, under the presidency of M. Renault, professor of the Faculty of Medicine of Lyon, and associate member of the Academy of Medicine. Dr. William J. Morton of 19 East 28th street, New York, is the American member of the general committee in charge of the congress, and from him further details may be obtained.

**Conferences theoriques et pratiques d'Electrologie, de Radiologie, et de Radiumologie.**—The Society of Medical Chiefs of the laboratories of radiology and electroradiotherapy of the Paris hospitals have organized a series of conferences to be held twice a year, in November and May. The second conference will be inaugurated at a meeting in the amphitheater of l'Hôpital de la Pitié, 83, Boulevard de l'Hôpital, Paris, on Monday, May 4, and will be followed by a series of lectures and clinics held in the same place daily for the ensuing month. Further particulars may be obtained by addressing Dr. Delherm, Hôpital de la Pitié, or Dr. Aubourg, Hôpital Boucicaut, Rue de la Convention, 62, Paris.

**Solly Tuberculosis Society.**—This society was organized on January 24, 1914, by the physicians of Colorado Springs, particularly those interested in the study and treatment of tuberculosis, with the following officers: *President*, Dr. Charles Fox Gardiner; *Vice-President*, Dr. Boswell P. Anderson; *Secretary-Treasurer*, Dr. Joseph J. Mahoney.

**Medical Association of the Greater City of New York.**—A special meeting of the association, under the direction of the chairman for the Borough of Queens, will be held at the Forest Hills Inn, Forest Hills, Long Island, on Monday, April 6, 1914, at 8.45 P.M.

**The Society of Sanitary and Moral Prophylaxis** will hold its annual meeting at the Academy of Medicine on April 9. Mr. Samuel Hopkins Adams will read a paper on "What the Quacks Are Doing," and Mr. Almuth C. Vandiver, counsel of the New York County Medical Society, will speak on "What Can Be Accomplished Under the Present Laws." State and local organizations will be represented in the discussion.

**St. Vincent's Hospital Alumni.**—At the next regular meeting, to be held on Wednesday evening, April 8, 1914, at the Yale Club, Dr. Charles Edward Nammock will read a paper on the "Management of Cardiorenal Disease."

**Medical Society Elections.**—TENTH COUNCILOR DISTRICT OF THE ARKANSAS MEDICAL SOCIETY: Annual meeting at Fort Smith on March 16 and 17. Officers elected: *President*, Dr. James A. Fergus, Rogers; *Vice-President*, Dr. Clark Wood, Fort Smith; *Secretary*, Dr. Arthur F. Hoge, Fort Smith; *Treasurer*, Dr. R. G. Carlin, Fort Smith.

RHEA COUNTY (TENN.) MEDICAL SOCIETY: The following officers have been elected for the ensuing year: *President*, Dr. James L. McKenzie, Graysville; *Secretary-Treasurer*, Dr. Arthur W. Gross.

**Obituary Notes.**—Dr. THOMAS A. ALLEN of Hendersonville, N. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1853, and a member of the Medical Society of the State of North Carolina, and the Henderson-Polk County Medical Society, died in Nashville, Tenn., after a short illness, on March 11, aged 89 years.

Dr. MARCUS M. JOHNSON of Hartford, Conn., a graduate of the New York University Medical College, New York, in 1877, and a member of the American Medical Association and the Connecticut State and Hartford County Medical Societies, died at St. Francis Hospital, Hartford, after a short illness, on March 15, aged 70 years.

Dr. WILLIAM WHATLEY BATTEY of Augusta, Ga., a graduate of the Medical College of Georgia, Augusta, in 1874, and a member of the American Medical Association, the Medical Association of Georgia, and the Richmond County Medical Society, died at his home, after a long illness, on March 12, aged 65 years.

Dr. JOHN T. JONES of New Orleans, La., a graduate of the Medical Department of the Tulane University, New Orleans, in 1880, died at his home on March 11, aged 53 years.

Dr. WALTER E. S. PRESTON of Newfield, Me., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1888, died at his home, on March 15, aged 55 years.

Dr. HERMAN FRED LANGE ZIEGEL of New York, a graduate of the College of Physicians and Surgeons, New York, in 1901, a member of the American Medical Association, the New York State and County Medical Societies, the Academy of Medicine, and the Associated Alumni of Mt. Sinai Hospital, and adjunct attending physician to Beth Israel Hospital, died at his home, on March 27, aged 38 years.

Dr. EUGENE G. WEST of Orange, N. J., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1884, and a member of the New Jersey State Homeopathic Medical Society, died at his home, from scarlet fever contracted from a patient, on March 28, aged 49 years.

Dr. EDWARD W. BLAKE of Tahlequah, Okla., a graduate of the Missouri Medical College, St. Louis, and a member of the Oklahoma State and Cherokee County Medical Associations, died suddenly at his home from heart disease, on March 13, aged 44 years.

Dr. E. B. UTLEY of Marion, S. C., a graduate of the College of Physicians and Surgeons, Baltimore, in 1883, and a member of the South Carolina and Marion County Medical Societies, died at his home, after a short illness, from pneumonia, aged 53 years.

Dr. THEODORE R. WAUGH of St. Albans, Vt., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1872, died at the Rood Sanitarium, Burlington, from nephritis, after a of the incorporators of the St. Albans Hospital. Waugh was at one time president of the Vermont State Homeopathic Medical Society, and was one of the incorporators of the St. Albans Hospital.

Dr. PATRICK SHEEDY BYRNE of Spokane, Wash., a graduate of the Bellevue Hospital Medical College, New York, in 1884, formerly a practitioner of Yonkers, N. Y., a member of the Washington State and Spokane County Medical Societies, and at one

time Mayor of Spokane, died at his home suddenly, on March 22, aged 58 years.

Dr. VINCENT G. HAMILL of New York, a graduate of the University of Buffalo, Medical Department, in 1884, died at his home on March 25, aged 51 years.

Dr. HARVEY JAMES SULLIVAN of Chatham, Ont., a graduate of the University of Toronto, Faculty of Medicine, in 1902, died at his home from pneumonia on March 18, aged 39 years.

Dr. CHARLES L. RANDELL of Waldoboro, Me., a graduate of the College of Physicians and Surgeons, Baltimore, Md., in 1889, died suddenly at Tampa, Fla., on March 22, aged 55 years.

## Obituary.

### EGBERT LE FEVRE, M.D., D.Sc., LL.D.

NEW YORK.

DR. EGBERT LE FEVRE, Dean of the University and Bellevue Hospital Medical College, New York, died at his home, after a short illness, from scarlet fever, on March 30, aged 56 years.

Dr. Le Fevre was born in Raritan, N. J., in 1858; he was graduated from Rutgers College in 1880, and from the New York University Medical College in 1883. He then served as an interne at Bellevue Hospital for two years, and in 1888 joined the Faculty of New York University as a lecturer on the practice of medicine. In 1890 he became professor of medicine, and in 1898, on the union of the New York University Medical College and the Bellevue Hospital Medical College, became dean of the college and professor of therapeutics and medicine. Throughout these years he had done much to raise the standard of medical education in New York.

At the time of his death, Dr. Le Fevre was visiting physician to Bellevue and the City Hospital, and consulting physician to the Red Cross, Beth Israel, Nassau, Nyack, Mt. Vernon, and North Hudson Hospitals. He was a member of the American Medical Association, the New York State and County Medical Societies, the New York Pathological Society, the Academy of Medicine, the Society of the Alumni of Bellevue Hospital, the American Clinical Society, the National Association for the Study and Prevention of Tuberculosis, and the American Climatological Society.

---

At a meeting of the Faculty, held March 30, the following minute was adopted:

"We, the Faculty of the University and Bellevue Hospital Medical College have learned, with the most profound sorrow, of the death of our Dean, Egbert Le Fevre, M.D.

"Dr. Le Fevre, by his learning and acute perception, gained the respect of all who knew him, and by his kindly thoughtfulness and justice secured the love of his students and colleagues.

"His enormous capacity for hard work was ever the marvel of his associates, and a constant stimulus to them, and in his death this institution has sustained a most grievous loss.

"In appreciation of his lovable character, inflexible integrity, and scientific attainments, the Faculty has spread this minute on its records, and directed that it be published in the lay and medical press, and a copy sent to the family."

S. A. BROWN, M.D., Secretary.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

RADIUM THERAPY—PAROXYSMAL TACHYCARDIA—SECONDARY LEUKEMIA—HEALING WELLS AND WATERS—PAINLESSNESS OF THE DEATH STRUGGLE—MEDICAL SOCIETY'S DINNER—OBITUARY.

LONDON, March 13, 1914

RADIUM therapy has been for some time a common topic of conversation even among those who do not expect to employ it themselves, although deeply interested as to the results obtained. Perhaps these may have more influence in shaping the general opinion than enthusiasts and those who leave it entirely to specialists to determine results. The discussion at the Medical Society of London, which had been looked forward to with much interest, came off on Monday night, in the most inhospitable weather—enough to keep at home anyone not obliged to turn out. But those prominently and earnestly engaged in radium therapy put in an appearance. The discussion certainly confirmed the opinion at present prevailing as to the use of the rays. It is almost universally held that for operable cases of malignant disease the proper treatment continues to be by operation. Only an insignificant minority think there can be any question whether radium can become an alternative to operation, while scarcely a larger number would suggest it as an adjunct. Yet though the effects of radium do not justify the use of the word cure, they are unquestionably of great therapeutic power. They relieve pain in a remarkable way; they often seem to arrest the progress of the disease, and in this way may be credited with prolonging life. The treatment is therefore being carried on in all directions, the chief hindrance being the excessive cost, but this, we are assured, is likely to fall. The idea of a ring to keep up the price is generally repudiated. Portsmouth has issued an appeal for £1,000 to buy radium for its hospitals, and the response was at once liberal.

Among disturbances of the circulation paroxysmal tachycardia offers puzzle enough to excite attention, the more so as cases are rare. One in a boy of two and three-quarter years was communicated to the medical section (R. S. M.) on the 24th ult. Dr. Robert Hutchison said on admission to hospital the heart was rapid, neck pulsating, and the liver was felt to pulsate also. The symptoms were said to have lasted ten days. They disappeared in two days, but three days later came on again as suddenly on sitting up in bed, the pulse rising to 245. This lasted twenty hours, and ceased as abruptly as before, the boy remaining quite well for ten days. Discharged from hospital June 26, 1913, kept well to September 22, on which day a third attack came on, lasting twelve hours, with a pulse of 215. On October 3 a fourth attack came on, with pulse 213. This lasted forty-eight hours, and there has been no relapse since. Dr. Parkinson showed the cardiograms which had been taken, and said the Wassermann reaction was negative.

Dr. Sutherland said the interest of such a case related to what might occur in future, but it is necessary to distinguish cases of tachycardia which are only paroxysmal from such as occur when the heart is diseased. Before these cases had been studied by late methods they had been attributed to tobacco, alcohol, tea, etc. He showed three cardio-

grams, one from a child of nine. He thought the auricle contracted before the ventricle had ended its contraction, which would account for the large venous wave seen in the tracings, as well as for the large pulsating liver. In one case he gave a child 45 minims of digitalis a day for nineteen days, with a view of producing a degree of heart-block and poisoning of the ventricle, so that it could not react to the too frequent stimuli of the auricle. Dr. Alexander Morison thought they could hardly say the rapidity began in the auricle, as if so digitalis would influence it as it did in fibrillation. He thought it began in the ventricle. Dr. Percy Kidd (presiding) related a case of a boy of four and one-half years who had attacks of blueness after measles at two. They came on about once a month and were followed by vomiting. In a late one the pulse was 240 and the liver enlarged, but the child was quite comfortable and happy. Digitalis did not affect the pulse, but caused vomiting. At one time the pulse continued rapid for six months without other symptoms, then suddenly edema, dyspnea, and cyanosis supervened, and he died. At post-mortem the heart was found dilated, and there was some hypertrophy of right ventricle and left auricle. No valvular disease.

Secondary or symptomatic leukemia was brought before the same meeting by Dr. Gordon Ward, particularly in reference to cancer with bone metastases. He holds that leukemias may be divided into primary and secondary like other anemias. In the former the blood-forming organs react to an unknown stimulus, which may very likely be excessive white blood destruction. In the latter the stimulus, whatever it may be, is so much the weaker, according to the degree of the disturbance of function. This secondary leukemia he divided further into two classes: (1) Lymphocythemic, which he said is mostly associated with septic diseases, and (2) myelocythemic, which is particularly associated with cancer.

The distinction could scarcely be as definite as he suggested, for he mentioned cases of this second subdivision in which sepsis was present. In neither of the secondary forms did a complete blood picture, as in the previous forms, appear. The conclusion he had reached was that there exists a condition of secondary leukemia, distinct from the primary form, and that it is analagous to secondary hemolytic anemia. Dr. Parkes Weber repudiated the proposed classification, and regarded the secondary cases described as merely varieties of leucocytosis. Dr. R. Hutchison considered there was no necessity for classifying leukemia as primary and secondary. Further, he thought that our present nomenclature of blood diseases would soon have to give way to a better one.

Healing wells and waters formed the subject of an address at the British Medical Society last week by Dr. D. McKenzie, who admitted that, like other primitive methods, they owed their reputation to qualities largely outside medical—so much so that he grouped them under the heads of magical, religious, and physical. Magical laving was used in skin and eye diseases from prehistoric times downwards. Religious water cures antedated the rise of worldwide religions, and continued in them. Lem-zem, at Mecca, the Ashlepian holy wells in Greece and Rome, were instanced, as well as the Pool of Bethesda. In his physical group a few more or less rational methods might be curative. In these the shock treatment by water of insanity and rabies was, he thought, interesting, and the baths—cold and vapor—practiced by Russians, American Indians, and the natives of Australia.

Many people are comforting themselves with the idea that death is usually painless, and not a few are asking their doctors if they can corroborate Professor J. C. Wilson, who lately took part in a correspondence in the *Times* on this question. He described the struggle for breath of his father, who was thought to be dying, as most harrowing to witness, though his doctor assured him that the patient was not suffering. His father survived until the morning, when he said he had had a very comfortable night, showing the correctness of the medical man. Other correspondents, among them Sir Henry Morris, have written to confirm the opinion that delirium and struggling are not manifestations of pain and that what people call the death agony is in most cases to the patient like dropping into a long sleep.

Sir David Ferrier, F.R.S., took the chair at the Medical Society's dinner on the 4th inst., and when proposing the toast of the society, spoke of the founder, Dr. Lettsom, whose merits as a rule form the foundation of most of these annual speeches. It is now one hundred and forty-one years since he established the society. The original members were ninety in number, equally divided between physicians, surgeons, and general practitioners, or as then called, apothecaries. There are now nearly seven hundred, who call themselves fellows. In the early days the rule was for each to read a paper in rotation or pay a fine of 5 shillings, or give a book of that value to the library, which now contains some 20,000 volumes. The seconder of the toast, which was of course duly honored, spoke of the society as the best meeting place for practitioners of every branch of the profession, where papers on every subject of medical interest could be discussed from every point of view.

The death of Sir Francis Xavier MacCabe, formerly medical commissioner of L. G. B. for Ireland, took place on Monday, at the age of eighty. He was the son of William MacCabe, the historical writer. From 1858-65 he was in private practice, then became medical superintendent of Waterford Asylum and later of Dundrum. In 1876 he was appointed inspector under the Irish L. G. B.; in 1885, member of the Prisons Board and inspector of reformatory and industrial schools In Ireland, retiring in 1885. He was on the Royal Commission of inquiry into the sanitary condition of Dublin in 1879.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

### A NEW PLAGUE OUTBREAK—UNITY OF YAWS AND SYPHILIS—GANGOSA.

MANILA, P. I., February 12, 1914.

DURING the last week of January a sharp outbreak of plague occurred in Manila. On January 24 there was a case reported at 105 Calle Alejandro, which is in the Echague district which has heretofore been infected. On January 26 a Chinaman living at No. 143 Calle Rosario was found with the disease. On January 27 another person was stricken at the same address. On January 31 a man and his wife were found dead at No. 675 Calle Echague. It is of interest to note that in the two latter cases a rat hole was found near the bed in which these persons slept and on prying up the floor under

their bed, several mummified rats were found which had all the appearance of having died of plague, although this could not be actually demonstrated by laboratory investigation. It is assumed that the fleas after leaving the rats found their way through the cracks in the floor and thus reached their victims. Later, three more cases of plague were discovered in different parts of the city and for several days it appeared that a general outbreak was imminent. After a thorough investigation, however, it was found that all of the latter cases were actual residents of the block on Calle Rosario in which the first cases had occurred and by transferring to other addresses they hoped to escape the sanitary measures which are carried out by the Bureau of Health. A sanitary cordon was immediately placed around the infected district and 100 rat catchers and laborers were put to work. The anti-rat measures began at the periphery of this zone and were conducted toward the center. In removing some double walls and ceiling in the house at No. 143 Calle Rosario, a number of mummified rats were found. In connection with this address there was also a large warehouse in which many tons of merchandise were stored. This warehouse also served as a living place for a large number of people, the larger boxes being used as beds. Cooking on a large scale was carried on in a small court yard. The conditions were indescribably insanitary.

No further cases occurred between February 3 and February 11. On this latter date a human case of plague was found at No. 206 Calle Juan Luna, which is within the sanitary cordon and located in the same block and the back abuts on the back of the premises of the cases reported at No. 143 Calle Rosario. The anti-rat measures in this house resulted in finding 65 dead rats in the ceilings, hollow partitions and under the floors. These rats are now being bacteriologically examined at the Bureau of Science. The foregoing experience again demonstrates the intimate relationship which exists between rat and human plague. It is of interest in this connection to mention that much of the merchandise found in the warehouses of the infected premises consisted of lamp chimnies and other glassware packed in straw which came from Japan. Plague has been almost continuously present in many Japanese ports during the past year and it is not improbable that plague infected rats or fleas may have been introduced with this merchandise.

The Manila Medical Society met at 8.30 P.M. February 2 in the amphitheater of the College of Medicine and Surgery. Surgeon C. S. Butler, of the United States Navy, read a paper entitled "Some Facts and Some Fancies Regarding the Unity of Yaws and Syphilis." Doctor Butler has made an extensive study of yaws in the Philippines and comes to his conclusions after a thorough study of the literature on the subject and from actual experience. Among other things he stated that after diligent search he was unable to find syphilis in a person who had been afflicted with yaws. He stated he was unable to throw any light on the observation which had frequently been made in the Philippines that yaws were more often found among residents of the interior than those who did not apparently come actively in contact with the outside world. The author was of the opinion that yaws is but one of the very many manifestations of syphilis.

The next paper was entitled "Gangosa and Other Mutilating Ulcerations, Their Relations to Yaws and Syphilis," by Capt. Ferdinand Schmitter, United States Medical Corps, and member of the Army Board for the Study of Tropical Diseases as they exist in the Philippine Islands. Dr. Schmitter also adduced much evidence which confirmed the conclusions of Dr. Butler. He was also of the opinion that gangosa is in all probability a manifestation of syphilis.

The next paper presented was entitled "Evidences of Syphilis Encountered in the Philippine General Hospital During One Year," by Dr. J. E. Reed, who stated that syphilis had been encountered in over ⅔ per cent. of the total number of cases discharged during the year. There had been more Filipino women admitted with the disease than Filipino males, but this he attributed to the fact that the inspection of dance hall women probably was responsible for a larger number of women applying for treatment. Otherwise, the percentages of the different form of the disease were much the same as found in general hospitals of the United States.

The last paper was one read by Dr. R. W. Hammack, of the College of Medicine and Surgery, entitled "Evidence of Syphilis Encountered in the Manila City Morgue During One Year." Dr. Hammack stated that among 712 autopsies, slightly over 3 per cent. of the bodies were found to be afflicted with syphilis. He prefaced his remarks, however, by the statement that the manifestations of syphilis were found in connection with routine autopsies which were carried out and that no special effort was made to look for syphilis. In the discussion which followed, the prevailing opinion seemed to be that syphilis, gangosa, and yaws were all one and the same disease, and one speaker stated that careful studies made by Dr. Noguchi failed to show any demonstrable difference between the organisms encountered in these diseases.

## CROTALIN IN EPILEPSY.

To the Editor of the Medical Record:

Sir:—Recently two notices have appeared of sudden deaths following the use of crotalin, a preparation of the venom of the rattlesnake, by hypodermic injection, and at the present time I am seeing patients who come to report the absolute uselessness of the drug in checking epileptic attacks. Thus in a boy of fifteen, seen recently, suffering from a typical idiopathic epilepsy, without any ascertainable organic origin, but with a history of epilepsy in both his mother's family and his father's, the use of crotalin injections every two weeks during the past six months has been attended by a steady increase in the number and severity of his fits, which now occur once a week, when six months ago they were occurring but once a month. This is not due to any suppression of bromides, as he had never been under bromide treatment. I have not seen any records of a trial of crotalin in any of the epileptic colonies where new suggestions for the treatment of this disease can be thoroughly tried, and it seems to me, from the lack of any reliable reports with regard to benefit obtained by the use of the drug, that there is every probability that this remedy is useless and even not free from danger.

5. Ileal Stasis. Report of Thirty-Three Cases. G. Blake.

**2. Strange Aspects of Whooping-Cough.**—P. H. Sylvester states that the death of a child from any cause is a tragedy; but one is liable to lose sight of this fact in the sudden, unexpected, or dramatic death of an unusual case. Whooping-cough, with a mortality of approximately 7 per cent., and a toll of ten thousand in the United States annually, presents an appalling contrast to the layman's, and the average physician's, conception of its harmlessness. The causes of death in whooping-cough are, briefly, exhaustion, pneumonia, bronchopneumonia, heart failure, and terminal tuberculosis. The cases which the author describes are of interest owing to their unusual type and provide an argument for an efficient treatment of, as well as prophylaxis against, the disease. Six of the eight cases reported were much alike. The author concludes from his experience that certain cases of whooping-cough have symptoms of intracranial pressure, best explained on the ground of a cerebral hemorrhage. The hemorrhage appears to be dependent upon the stress of a severe paroxysm. The symptoms of hemorrhage in these cases pointed to lesions other than middle meningeal and were surprisingly uniform in the initial convulsion, immediate rise in temperature to a high degree, cyanosis, and spasticity rather than paralysis. This type of cases emphasizes the importance of prophylaxis. Treatment should be directed toward at least reducing the severity of the paroxysms.

**5. Ileal Stasis.**—G. Blake from a study of ileal stasis concludes that ileal stasis is found: (1) as a pathological entity; (2) as a symptom of other pathological conditions; (3) as a coincident condition in other diseases to which it is not apparently related. Constipation and epigastric pain soon after meals are the commoner symptoms. The stomach-contents analysis is of little or no value in making a diagnosis. Two cases only were of the typical primary ileal stasis type—those diagnosed constipation—although the cases of neurosis and debility (five in number) might be considered as possibly belonging to this type. No case of Lane's kink was found. The treatment is by choice the relief of constipation by Russian oil or agar or both, together with hygienic and tonic treatment, the mechanical support of ptosed structures and correction of faulty posture, and surgical operation. The diagnosis of the condition is made by bismuth *x*-ray examination.

**2. The Abderhalden Reaction in Psychiatry.**—B. Holmes states that the Abderhalden reaction now furnishes a means of the serological diagnosis of dementia præcox, a condition which makes up about one-fifth of the admissions to hospitals for the insane. The test enables one to differentiate dementia præcox from manic depressive insanity, and from hysteria, which furnish more than another fifth. The reaction is also of very great assistance in separating the non-syphilitic from the syphilitic insanities, and suggests a rational interpretation of many of the symptoms in all forms of psychosis.

**4. Relaxed Ear Drums.**—H. Hayes points out that the majority of otologists are wont to consider that almost all cases of deafness are due to a catarrhal condition, causing retraction of the drum or a stiffening of the ossicular joints. By the careful use of an electric otoscope, to which a massage apparatus can be attached, one will observe that in many cases of deafness the ear drum, although retracted and thickened, is often at the same time relaxed. At least fifty per cent. of the patients who come to the otologist suffer more from a relaxed drum than from a retracted one. The important indication is to bring back the drum to its proper tension and to tighten the ligaments between the ossicles by creating an inflammatory reaction, which, when it subsides, will not have done any particular harm, but at the same time will have created a certain amount of connective tissue infiltration. The success of the treatment is due to the daily application of irritating fluids to the ear drum, so that it remains inflamed over an extended period of time. As the drum becomes more and more irritated and inflamed, a thickening occurs, which thickening draws on both the circular and straight muscular fibers of the drum, and instead of retraction, the membrane is drawn out until it assumes a more normal position. This tightening is always more noticeable around the circumference of the drum and its attachment to the annular ligament. The joints between the small bones of the middle ear having been more or less ankylosed, as the drum is drawn out, there is a tendency for these joints to loosen up. This lengthens the ossicular chain, with the result that more tension is put upon the ligament of the oval window. This tightening up of the drum, however, the author says, cannot be obtained in a short time.

**5. Etiology and Treatment of Infantile Wasting.**—H. Lowenburg reports three cases of this condition. He states that it seems to be brought about as the result of some error in body chemistry depending initially upon the abnormal activation of the salivary glands by a food abnormal for the individual. Wasting in infants may depend upon syphilis. Commonly called baby's consumption, wasting in infancy may actually depend upon tuberculosis. A comparatively common cause of wasting in infants, frequently unrecognized and regarded as simple marasmus, is obstructive disease at the pylorus. The main features of this condition, beside the progressive loss in weight, are vomiting, propulsive in character, beginning immediately or shortly after birth; partial or complete constipation; visible gastric peristalsis and palpable pylorus; delayed progress of the passage of charcoal through the alimentary tract or its total absence in the anal discharges and its appearance in the stomach washings twenty-four hours after administration; and characteristic *x*-ray pictures, showing the partial or complete retention of the bismuth meal in the stomach. These symptoms make up a typical picture of a distinct clinical entity, yet they are often passed by. Many of these cases would end favorably by operation, but are allowed to terminate fatally upon some pet milk formula or an array of proprietary or other foods sufficient to sustain an army. Here a discriminating diagnosis would be life saving.

**1. Subcutaneous Injection of Crotalin.**—J. F. Anderson states that rattlesnake venom was recommended by Spangler in 1910 for epilepsy. Since Spangler's paper there have appeared reports of its use for other conditions, including tuberculosis. The author reports a fatality following the use of crotalin. He points out that a sterile solution cannot well be assured. Weir Mitchell many years ago alluded to the great possibility of a secondary infection in a survivor in acute rattlesnake poisoning and also called attention to the rapid decomposition following death by snake poison. Welch and Ewing in 1896 showed that rattlesnake venom almost completely destroys the bactericidal properties of the blood and this has been confirmed later by Flexner and Noguchi. The laboratory findings in the case reported left no reasonable doubt that the death was due to the presence in the crotalin solution of pathogenic bacteria which were also shown to be present in the other ampoules in the same lot as those used. There were tested for sterility ninety-five ampoules of crotalin solution, prepared by four different firms, thirty-five of which (38.8 per cent.) were found not to be sterile. In the great majority of instances the contamination of the crotalin was found to be with anaerobic organisms and to all appearances usually with a certain anaerobic bacillus. Every tablet (twelve) examined was found not sterile and while more than one organism was present an anaerobic bacillus was found in every one.

**2. The Influence of Diet on Hepatic Necrosis and Toxicity of Chloroform.**—E. L. Opie and L. B. Alford conclude that fat administered to animals and presumably stored in part in the liver increases the susceptibility of the organ to the injurious action of chloroform. In view of the well-known solubility and diffusibility of chloroform in fats, the authors suggest that the fat of the liver cell determines the fixation of chloroform and the occurrence of necrosis. The experiments with carbohydrates, on the contrary, furnish confirmation of the views of those who maintain that carbohydrates protect the body proteins from disintegration. Since necrosis of the liver with a variety of conditions in man, namely, toxemia of pregnancy, acute yellow atrophy of the liver, yellow liver, and poisoning with a variety of substances, exhibits close similarity to the necrosis of chloroform, the authors' experiments suggest that a carbohydrate diet may be found to influence favorably the course of these diseases, whereas fat may have grave danger.

**4. Artificial Pneumothorax.**—M. Schaie reports his experience with forty-five cases in which artificial pneumothorax was employed. In eight cases brilliant results were obtained in the marked reduction in temperature, the pulse-rate, the sputum output, the gain in weight, etc. In three other cases active and advancing processes were arrested and the patients continued to do well. In six cases the author failed to introduce gas into the pleural cavity in spite of repeated attempts. In one of these cases the Brauer method was used, an incision having been made down to the parietal pleura in one interspace, and a mass of adhesions with small pockets was revealed. One point especially impressed the author, namely, the persistent loss of weight in many cases in spite of improvement of symptoms. This occurred in eighteen of the cases, and in four of these the patients began to put on weight as soon as the treatment was discontinued. As regards dosage, every case is a law unto itself. The first guide is the comfort of the patient. The pleural injection is stopped as soon as any pain or dyspnea is felt. Secondly, it is guided by the manometer. The author never lets gas flow into the chest till good oscillations have been obtained. At first he inflates every two to five days till a fairly good pneumothorax is obtained. With a complete pneumothorax he waits from ten days to a month before performing reinflation. The author says, "We are influenced in determining the intervals by the following additional factors: the position of the heart, the patient's comfort, the presence of subcutaneous emphysema and the temperature range. In regard to the last-mentioned we inflate as soon as we see the curve rising again; with regard to comfort, as soon as cough and expectoration increase. Expectoration is frequently increased after the initial inflations with a diminution in cough. This applies particularly to cases in which there are large vomicæ. In these cases the patients expectorate larger amounts at one time and with greater ease. In the others cough and expectoration seem not to be influenced so much. In quite a few cases expectoration has fallen as low as from 15 to 25 grams in twenty-four hours and still the cough has continued to be severe for a long time. In the presence of subcutaneous emphysema we never reinflate, waiting for its complete subsidence." The fluoroscope has been of value in the detection of small effusions. Special details in regard to a number of the cases are given. Nine deaths occurred and in one of these the necropsy findings are reported. The deaths were of advanced cases or of those patients who had complications of the pulmonary disorder.

**6. Subacromial Bursitis.**—By L. W. Littig. (See MEDICAL RECORD, March 7, 1914, page 452.)

**14. The Sugar-Content of the Blood.**—F. C. McLean describes the method of finding the sugar-content of the blood and points out the clinical value of its determination. The method of Bertram is most accurate for the determination of glocuse in small amounts. The amount of sugar in the blood does not exactly correspond with that in the urine which has been customarily tested by clinicians, and the blood test is of value aside from its physiological interest, especially in the diagnosis, prognosis, and control of treatment in cases of diabetes mellitus. The finding of hyperglycemia alone does not prove the existence of the disease, as its transient occurrence may be due to other causes. If, however, it remains persistent after the withdrawal of carbohydrates from the diet for twenty-four hours or more, the case should be regarded as diabetes, even if the glycosuria disappears. Excessive sugar in the blood is the primary condition, and the tolerance to carbohydrate should be determined by its behavior. A pa-

tient may have a constant blood sugar-content of 0.18 per cent., or even more, without sugar in the urine. The diet should be regulated accordingly and not depend on the urinary finding. The blood examination may also help the prognosis in these cases, for, as recently shown by Frank, in most cases of glycosuria in pregnancy, the blood sugar remains normal or is even diminished following the purely renal character of the disease. In cases of transient hypoglycemia and hypoglycosuria blood examinations may be valuable in the diagnosis as well as in cases of cerebroglycosuria which may have to be distinguished from diabetes.

**15. Benzol Treatment of Leucemia.**—F. H. Smith reports two cases of leucemia in which benzol was used. He gives a review of the literature of the method and calls attention to its possible dangers, which have also been noticed by various other authors. He calls attention to the fact that benzol is benzene, not benzine. Its formula is $C_6H_6$. Its toxicology has not been completely worked out, and there is no definite dosage of the drug. Koranyi begins with a dose of 0.5 gram., increasing this until some effect on the blood picture is shown, and it seems that for safety a constant recourse to blood examination should be taken. In most of the reported cases the Roentgen ray seems to have been used some time before the benzol, the assumption being that the Roentgen treatment prepares the way. In the cases reported by the author there was no Roentgen treatment. Summarizing his impressions, he states that there can be no doubt that benzol is a remedy of remarkable potency in myeloid leucemia. Benzol accomplishes feats hitherto undreamed of in the rapid subsidence of signs and symptoms in a fatal disease. But it is a two-edged sword and he who uses it without bearing in mind its grave possibilities is running the serious risk of substituting for one disease a still more fatal one. One has as yet no proof that benzol is a specific, and it is significant that not one clinician has yet expressed himself with reference to the future of these patients. The author hazards the guess that within the next six months the journals will contain numerous reports of recrudescences of the disease after benzol suspension.

7. Recurrent Intussusception: with Suggestions as to the Etiology. H. T. Gray.

**1. Changes in the Blood in the Causation of Surgical Shock.**—A. Rendle Short made a series of analyses of carbon dioxide in venous blood in human cases of shock, as the result of which he concludes that acapnia is not the cause of ordinary surgical shock. One is still left face to face with the problem of a falling blood pressure with a normal heart and with contracted arteries. Analyses showed that adrenalin exhaustion is not the significant factor in the causation of shock. The suprarenals are by no means exhausted. In two cases the adrenalin was as high as, or higher than, in the controls. According to Cevidalli and Leoncini, the adrenalin content measured by a colorimetric test, is low after a chronic illness. Anesthetics are said not to affect it. The author suggests that the nociceptive impulses which bring about surgical shock do so by inhibiting or paralyzing the important nuclei in the region of the fourth ventricle and perhaps in the cerebellum, which, as Sherrington and others have shown, are continually sending impulses down the spinal cord, maintaining its functional activity and increasing muscular tone. When such inhibition or paralyses take place the functions of the cord are greatly reduced, tone is abolished, and therefore, as a secondary result, the blood pressure may fall. The respiratory center, and perhaps even the vasomotor center, share in this inhibition or paralyses; this is a very different conception from that which regards exhaustion of the vasomotor center as the prime cause of all the symptoms. Death is due to the accumulation of blood in the great veins, so that the *vis a tergo* is no longer able to provide a proper filling for the heart, especially as the feeble respiratory movements fail to exert their important pumping action. A very striking example of this sequence is met with in what is called the "knock-out blow" in pugilism, or rather in one of such blows. A vigorous drive on the point of the lower jaw in a line from the chin to the condyles is transmitted directly to the labyrinth of the internal ear, and by way of the vestibular nerve impulses reach the nuclei referred to by the author. As a result a powerful athlete is immediately reduced to a mass of quivering unstrung flesh, and may die outright. In a word, he is in a state of shock.

**2. The Agglutination of M. Melitensis by Normal Cow's Milk.**—P. W. Bassett-Smith states that the milk from cows in London is in some cases able to cause agglutination of the *M. melitensis* as lately pointed out by Kennedy. The latter found a positive reaction with the milk of three out of twenty-two cows, and five times from mixed milks. The reaction was also obtained when using whey, but was diminished or altogether lost by filtering the milk through a Berkfeld or Doulton filter. The author, using a forty-eight hours' culture for the emulsion and a dilution of one in twenty in this series, found that none of the milk from twenty-one cows gave a positive reaction when examined quite fresh, but with mixed samples of milk a high proportion reacted positively at this dilution. In any case it is necessary to centrifuge the milk very thoroughly and to examine it at once, using an emulsion made from the *M. melitensis* not more than forty-eight hours old, and even then a few errors will occur by false clumps in the sedimentation tubes carrying down micrococci with them. There is no doubt that cows' milk in some cases has a natural tendency to agglutinate the *M. melitensis*, but if care is taken most of these non-specific reactions may be avoided. The reaction should always be controlled by other methods of diagnosis before an animal can be considered to be infected.

**1. The Diagnosis of Tabes Dorsalis.**—G. Holmes concludes that the characteristic subjective demonstrable disturbances of sensation are usually the earliest, the most important, and the most unequivocal clinical signs of tabes dorsalis; that they are frequently associated with loss of the deep reflexes, especially of the ankle-

jerks and knee-jerks, and with pupillary, ocular, and other less frequent symptoms and physical signs; and that modern serological, cytological, and chemical methods can supplement and confirm the clinical diagnosis based on these clinical signs, and thus make the positive or negative diagnosis of tabes dorsalis as absolutely certain as anything can be certain in clinical medicine.

2. **The Treatment of Syphilis of the Nervous System by Intrathecal Injections.**—H. Campbell believes that in parenchymatous syphilis the intrathecal treatment is the only one yet devised which is capable of arresting the morbid process. It acts by destroying the spirochetes within the central nervous system and the cerebrospinal fluid. The treatment should be begun as early as possible. Neurons, once destroyed, are incapable of regeneration. Unfortunately, cases of general paralysis and tabes rarely come before one until wide tracts of nervous tissue have been irretrievably damaged. The intrathecal treatment is also indicated in cases of interstitial syphilis, especially of the spinal cord, which cases do not readily respond to salvarsan, mercury, or idodide of potassium. The last drug should be given in not less than dram doses three or even four daily.

## Deutsche medizinische Wochenschrift.

*March* 5, 1914.

**Internal Disinfection.**—According to Roosen this possibility has become identified with the diseases caused by protozoa. In this realm internal disinfection has been accomplished by quinine in malaria, arsenic in trypanosome diseases, and mercury in syphilis, as predecessors of Ehrlich's great invention of the synthetic salvarsan as a second specific for syphilis. Attempts to reach bacteria in this matter have not been a success. Methylene blue received a thorough test in this connection, both alone and in combination with mercury and silver. The small disinfecting power of certain substances is attributed not to the substances acting through powers residing in the molecules, but to the activity of their ions. The author from this viewpoint, has gone back to methylene blue as such a substance and has sought to combine it synthetically with calomel. An albuminate of mercury forms in the blood, and taking up the chlorine ions of the mercury changes calomel to sublimate. Methylene blue has a notable affinity with the nervous system, uniting with it chemically. Thus substances which cause staining *in vivo*, like methylene blue and eosin, seem to be those upon which reliance must be placed to act upon the cancer cell. Methylene blue has long been tested on tumors, but doubtless needs the aid of a tumor cell poison not severe enough to attack ordinary tissues. The problem has not yet been worked out in the case of human cancer patients but Roosen says that Professor Czerny intends to supply this demand in the near future.

**Hyperkeratosis Gonorrhoica.**—Lange reports a rare case of this general cutaneous outbreak of the gonorrheal virus. The first case was published in 1893 and quite a series of observations are now upon record. As a rule we note a balanitis circinato as the essential manifestation; but the palms and soles are sometimes involved and occasionally other portions of the surface. The affection is usually attendant on a multiple gonorrheal arthritis. In regard to the varieties in localization Baermann would make two forms, one a generalized exanthem, and the other conglomerate lesions on palms and soles, and especially between the digits, and under the nails. A case by the author brings out many of the points made in Baermann's description and adds new ones. Thus a young man, already a victim of familial muscular atrophy was infected for the first time with gonorrhea. Joint manifestations appeared early, chiefly in the ankles, feet, and toes. The coincidence may be cited that his feet were in the talipes equinus position as a result of the muscular atrophy. The balanitis circinata developed, and later upon the soles of the feet and toes appeared numerous efflorescences varying much in size which soon became horny. The author does not believe the feet would have shared in the outbreak had not the deformity paved the way. No gonococci could be found in the lesions.

## Münchener medizinische Wochenschrift.

*March* 3, 1914.

**Abderhalden's Dialysis Procedure.**—The above number of this journal contains a symposium on this subject. Mandelbaum deals directly with the peptolytic enzymes of the blood and cells and learns that every organ and every tissue, and every cell contains a ferment which splits glysyltryptophan. During life this ferment is held by the cells with the greatest tenacity. Whenever cells perish rapidly the ferment appears in the blood, but in slow death of the cell the active properties are lost. These enzymes should stand in some close relationship with Abderhalden's proteolytic protective ferments. Lampé continues his work on the specificity of the defensive ferments of Abderhalden. He alludes to 10 cases of anemia and chlorosis in which he sought for the latter and found no evidence of activity of any organ of internal secretion, although ferments which break up ovarian substance have been alleged to be present in chlorosis. As a general conclusion, however, in individual disease pictures enzymes can be demonstrated in the blood and serum which have to do with definite organs. In Graves' disease the thyroid, thymus and ovary; in myxedema, the thyroids; in endemic goiter, the same; in acromegaly, genitals and hypophysis; in eunuchoidism, testicles; in Addison's disease, the adrenals. Ferments in all these cases are formed which are able to break up the corresponding organ. As regards Abderhalden's diagnostic procedure it has thus far been of clinical service in differential diagnosis—between epileptic and hysterical convulsions, between hysteria and tuberculosis, etc. —but its greatest repute is in its ability to diagnosticate outright both pregnancy and cancer. Flatoa says in regard to pregnancy diagnosis that pregnancy serum is not the only substance which can break down placental tissue. The proteolytic ferments of normal blood serum cleave the organ albumin of the placenta in a fully nonspecific manner and without quantitative rules. Kämmerer, Clausa, and Dieterich discuss the dialysis procedure *per se*, and state as their belief that its chief weakness lies in the want of uniformity of the shells.

**Intravenous Injections of Gonorrheal Vaccine.**—Habermann concludes an article on this subject as follows, referring to the long-known serum of Bruck: There appears to be neither diagnostic or therapeutic superiority of the intravenous method over the intramuscular. The sharp, brief febrile reaction soon after the injection is sometimes seen in the normal subject, and hence is by no means specific. An evening rise of temperature and persistence of the fever on the following day points to gonorrhea. The strong collateral effects —fecal or general reaction, relapses, etc.—make it necessary, Habermann says, to lower the initial therapeutic dose and increase the same very slowly and cautiously.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### THE DETERMINATION OF THE BLOOD PRESSURE.

A REQUIREMENT for the taking of the blood pressure is comprised in an increasing number of the blanks for application for life insurance, and it is, therefore, important that the procedure be standardized as far as possible. Reports may vary according to the personal equation of the examiner, the apparatus used, and the method employed.

(1) The personal equation exercises an important part in the reading of the blood pressure. The tactile sense is more or less keen in different individuals and it is common to find the estimates of two observers from 5 to 10 mm. apart.

(2) The apparatus employed is responsible for many of the errors in reporting blood pressure. Instruments of all grades are being exploited by the manufacturers, but the first thought in the mind of a purchaser should be to secure a sphygmomanometer that is undoubtedly accurate, reliable and easy to care for. It is a simple matter to make the large bore standard mercurial instruments suitable only for office use, but much difficulty has been experienced in the construction of a compact and durable apparatus that is portable. The most satisfactory form of portable mercury instrument on the market at present is that having a short closed tube with mercury working against the enclosed air. The best of these instruments have the bulbous air space protected by a vacuum chamber against temperature variations, and the tube being closed at both ends prevents the entrance of dust and reduces the oxidation of the mercury to a minimum extent. One trouble with the portable mercury apparatus arises from the narrow caliber which is necessary in small instruments; errors due to the defective tubes, found frequently in cheap commercial sphygmomanometers, are accentuated if the caliber is small. The result of the oxidation of the mercury, also, is manifested sooner in the small caliber tubes. Still another objection is the shortened millimeter scale by which an otherwise small error in reading the blood pressure may be magnified. Glass tubing of uniform caliber cannot be blown, and defects in cheap instruments made from inferior glass tubing, cause a deviation of from 5 to 20 mm. from the correct reading. With so many elements of what constitutes a good sphygmomanometer to consider, it is wise to confine the choice to one made by a maker well known for reliability, regardless of the price.

The cuff must be at least 12 cm. in width, of leather or some stout material, with a bag made of material which will not harden.

Our experience with sphygmomanometers dates back to the time when these instruments came into use for life insurance work, and we have found the metal aneroid or diaphragm instrument, though not perfect, to be the most compact, portable, and reliable apparatus obtainable and still hold to that view. The great objection to it is that comparison with a large stationary mercurial manometer is absolutely necessary at least once a month. If no standard instrument is conveniently at hand to check up the aneroid frequently, a mercurial instrument should be used in preference. The aneroid instruments have been improved materially in the way of appliances for adjusting, and compensation can readily be allowed for changes in elasticity of the drum and spring.

(3) The method of taking the blood pressure should be standardized so that any number of readings taken on one or several persons by one or different operators, will bear a proper relation to each other.

The unreliable practice of determining the blood pressure by noting the return of the pulsation through the tactile sense of the finger tips will give way to the more delicate and exact auscultation method. The ordinary stethoscope may be employed, but this will not be necessary if the flimsy tubes and earpieces usually attached to the auscultation apparatus to insure portability are constructed on the more approved plan of the regular stethoscope.

The pressure should be determined as soon as possible after the vessels have been constricted by the arm band. If the constriction is prolonged, there will be a fall of several millimeters, according to the length of time, the fall beginning in about one minute. It has been stated that the pressure rises under such circumstances, but according to the long experience of the writer, this occurs only when the applicant is becoming excited. If further readings are desired, the arm band should be taken off and re-applied in about 10 minutes.

All blood pressures in life insurance examinations should be uniformly taken with the applicant in the sitting posture, this position being the most natural and convenient one to assume at such a time. The applicant should sit with the arm resting on a table with the muscles relaxed.

When a pressure higher than normal is obtained, several successive readings should be taken on different days to eliminate nervousness, excitement, recent energetic exercise, or a heavy meal as the causation of the high pressure.

Inquiry is frequently made as to why so many of the companies omit to ask for the diastolic pressure. There is no question but what the diastolic and pulse pressures are important data to the clinician. It is, however, felt in many quarters that there is not sufficient significance attached to the diastolic pressure for life insurance purposes, and that we do not know enough about it to justify the addition of this requirement to the medical examination. Furthermore, the determination of the diastolic pressure by palpation is unreliable and inaccurate, and it will not be practical in any event to exact it until the auscultation method is commonly understood and practised.

The auscultation method is generally recognized as the more correct and reliable procedure for determining the systolic as well as the diastolic blood pressure, and it is probable that the palpation method will soon be regarded as obsolete. In comparing the results with those obtained by the palpation method, an allowance of about 10 mm. should be made on account of the greater delicacy secured through auscultation. The arm band should be carefully adjusted in the proper place on the bare arm; if not, the sounds may become weak enough to escape the hearing of the observer.

In closing, it may be added that an error of 5 or 10 mm. may be unimportant for life insurance purposes when the pressure is very high or at a medium normal figure, but when it is near the border line it is imperative to have a correct report.

State Laws Limiting Marriage Selection, Examined in the Light of Eugenics. Eugenics Record Office Bulletin No. 9. By Charles B. Davenport, Carnegie Institute of Washington, Department of Experimental Evolution. With Two Figures and Four Tables. Price 40 cents. Cold Spring Harbor, June, 1913.

At a time when so much is being said and written about eugenics, the appearance of a bulletin such as this, in which the various State laws relating to marriage selection are analyzed from the viewpoint of eugenics, is to be welcomed as an important guide to this subject. In other words, a study of the biologicaal basis of marriage laws is provided particularly for the benefit of legislators who would frame additional laws to improve marriage selection. The author wisely points out that the reproduction of the feeble-minded will not be diminished to any great degree by laws that forbid the issuing to them of marriage licenses. From the viewpoint of eugenics the marriage of a mentally vigorous man with a socially attractive and beautiful, though defective, woman is permissible. Legislation against marriages of the insane is regarded as ineffective because in most cases the onset of the trouble comes after marriage. The laws restricting marriage take little account of the degrees of insanity. In the traumatic forms of the latter the eugenic significance is slight. The procreation of the insane, of course, cannot be prevented by legislation. They should be under custodial restraint during the entire reproductive period, which restraint would be more effective than legislation in limiting procreation. The kinds and degrees of insanity should be taken into account in all legislation of this nature. As regards the laws limiting consanguinity in marriage, the author points out that a large number of these prohibitions have no biological justification, for in many instances there is no blood relationship between the individuals whose marriage is prohibited. The marriage of first cousins is prohibited in twenty-two States and in Porto Rico. But the marriage of first cousins is not injurious to the offspring unless the stock is weak. Hereditary forms of feeble-mindedness are particularly apt to be perpetuated by such cousin marriages in tainted families, even though the parents themselves may be normal. One of the most important parts of this book is that which deals with the program of State eugenic control. It is suggested that three sets of officials are necessary for this control: a State eugenics board; State official physicians, who shall also issue marriage licenses; and field workers. The last would perform a function similar to that of the inspectors of life insurance companies. They would inquire into the mental and physical conditions of the families of the applicants for marriage licenses. The following drastic legislation is advocated: "For those persons who, despite a denial of marriage by the State, cohabit and have a child, the penalty should be sterilization of the male." Why should the male be singled out as the one to be sterilized when the female may be the one equally or even solely at fault? Similarly the following sweeping regulation is proposed: "With the eugenics board should be left the execution of all laws limiting procreation, both inside the marital relation and outside." It would be interesting to learn how such a board can regulate extramarital procreation.

Die Anwendungsweise der Lokalanästhesie in der Chirurgie. Auf grund Anatomischer Studien und Praktischer Erfahzungen. (The use of local anesthesia in surgery, based on anatomical studies and practical experiences.) By Prof. Dr. Fritz Hohmeier, Marburg. Introduction by Prof. Fritz König. With 54 Illustrations. Price 4 M. Berlin: August Hirschwald, 1913.

Notwithstanding numerous improvements which have attended the employment of general anesthesia there are still many dangers in its administration. To overcome certain of these, spinal anesthesia was introduced and practised with success by many operators, but notwithstanding its advantages this method is likewise accompanied by dangerous complications which have prompted a number of well-known operators to give up its use entirely. This state of affairs has led to the further development of local anesthesia and an increasing number of operations successfully done under its influence have served to show the value of the same. The writer of this manual has been largely identified with the development of local anesthetic methods in König's Clinic at Marburg, where over 50 per cent. of all surgical cases are operated on by this means. Hohmeier has added a great many new features in the application of local anesthetic measures, particularly on the extremities. The book is divided into two portions, in the first of which are considered the directions for the employment of the method. In general, this consists of blocking the nerve trunks in the immediate vicinity of the field of operation by perineural injections supplemented by the infiltration of the immediate subcutaneous tissues above the operative field and around the line of incision. In operations on the extremities the author has developed a special method of infiltration which is carried around the limb. Local anesthesia should be restricted to patients who are not fat or extremely nervous. The administration of a sedative on the night before operation, and a small dose of morphine subcutaneously a half hour before the same, are always indicated. Scopolamine and opium derivatives are not recommended. The author advises the exclusive employment of a .5 per cent. solution of novocaine combined with suprarenal extract, solutions of which should always be freshly prepared. In the second portion of the book are discussed the various operations possible with local anesthesia, including those on the head, neck, chest, abdomen, upper and lower extremities. The various gynecological, ophthalmological, otological, and dental operations are not included for present lack of experience. A large number of excellent anatomical plates from well-known sources are inserted and also diagrammatic explanations of the sites of injection for the various procedures. The work constitutes an excellent compact manual in practical surgical technique which must be seen to be appreciated.

Outlines for Case Taking and Routine Ward and Laboratory Work as used in the medical Clinic of Washington University. By George Dock, A.M., M.D., Professor of Medicine, Washington University. Price 25 cents. Ann Arbor, Mich.: George Wahr, 1913.

These are outlines for (1) miscellaneous cases and acute infections, (2) diseases of the respiratory organs, (3) of the circulatory apparatus, (4) of the organs of digestion, (5) chronic constitutional diseases, and those of metabolism, (6) diseases of the urinary and sex organs, (7) of the nervous system. Further there is a scheme for the examination of sensibility after Head and Holmes, and for the routine ward and laboratory work in medical wards.

Das Chronische Partielle Herzaneurysma, Anatomie, Klinik, Diagnose. Von Prof. Dr. Maximillian Sternberg, K.K. Primärartz am Krankenhause Wieden in Wien. Mit 10 Abbildungen. Price 3 Mks. Leipzig und Wien: Franz Deuticke, 1914.

This brochure contains the history, pathology, synthesis, variations from the typical syndrome, diagnosis, therapy, and prophylaxis of this condition. There is an extensive bibliography at the end.

Practische Winke für die chlorarme Ernährung. Von Prof. Dr. H. Strauss, Director der inneren Abteilung des Jüdischen Krankenhauses im Berlin. Zweite, vermehrte und verbesserte Auflage. Price, Mk. 1.50. Berlin: Verlag von S. Karger, 1914.

This practical guide tells of the indications for prescribing a diet poor in chlorides. Estimation of the chloride tolerance is given; also general and special principles governing the successful application of the diet; tables showing the salt content of the various articles of food.

Practical Prescribing, with Clinical Notes. By Arthur H. Prichard, M.R.C.S., L.R.C.P., R.N. (Retired), late House Physician, the Brompton Hospital, and Resident Surgeon, R. N. Hospital, Gosport. Price $2.00. London: Henry Frowde and Hodder & Stoughton, 1913.

In this volume the author attempts to bring diagnosis and treatment into somewhat closer relationship than often obtains. He selects a number of typical cases of the more common diseases, and gives suitable prescriptions, with explanations and comments. He further gives reasons for employing the various constituents in these prescriptions, pointing out their particular action in the given cases, and drawing attention to special points. The work is well done, and is calculated to make the reader think. As an introduction to practical therapeutics the book should prove of much value; it is both interesting and stimulating.

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

*Annual Meeting, Held January 19, 1914.*

THE PRESIDENT, DR. REYNOLD WEBB WILCOX, IN THE CHAIR.

**Election of Officers.**—The following officers were elected: *President*, T. S. Southworth; *Treasurer*, Isaac Hartshorne; *Chairman for the Borough of Manhattan*, Thomas Darlington; *Chairman for the Borough of Queens*, L. H. Moss; *Member of the Council*, F. H. Daniels.

**A Case of Osteitis Deformans.**—Dr. J. HERMAN BRANTH presented a male patient, 50 years old, who exhibited all the typical signs of this disease, as first described by Paget in 1877—enlargement and softening of the bones, especially of the long bones, which showed curvature, and of the bones of the cranium, kyphosis, and stiffening of the tendons of the femoral muscles and the joint ligaments. The patient also had nystagmus, though this had now almost entirely disappeared under the experiment treatment employed. This, Dr. Branth said, consisted of the application of *x*-rays to the head and lumbar region and the use of the high-frequency, high-tension current. At first he had intended to give pituitary extract also, but as the patient's condition seemed to have taken a favorable turn under the electrical treatment alone, this would be continued for the present. Nothing was known of the etiology of osteitis deformans, and the disease did not prove fatal; the patients dying from old age or some intercurrent affection.

**An Inflating Gastroscope and Duodenoscope for Inspection of the Organs through the Gastric (Gastro-enterostomy) Incision.**—Dr. ROBERT COLEMAN KEMP read this paper, which was written by himself and Dr. Albert Vander Veer, Jr. The gastroscope was based, he said, on the principle of Tuttle's inflating proctoscope, but the light was situated inside the tube, so as not to interfere with the spherical clamp, and there were on the instrument six projecting rims, one inch apart. By means of these rims at intervals one could insert the tube to different distances, and thus explore the entire stomach. It was found by experiment that a light at the tip of the instrument was preferable to one reflected from near the eye-piece. The inflating bulb was that employed for the Tycos sphygmomanometer. The length tof the gastroscope was 6 inches, while that of the duodenoscope was 12 inches. The inflating tube in the latter was directly attached to the main tube by a branch, thus allowing more space for the eye-piece. In these instruments the principle of the operating cystoscope was simplified. The tungsten light was used, and the apparatus afforded a practical method of internal inspection of the stomach at the time of abdominal section. The surgeon was frequently dependent upon his sense of touch for the determination of the location of existing lesions. It was sometimes impossible to detect an indurated ulcer on the posterior surface, by the method of palpation, while a non-indurated one would usually not be discovered at all. Gastroscopy previous to operation was very unsatisfactory unless performed under general anesthesia, and an additional complete anesthesia before a capital operation was objectionable in many cases; as was also prolonged anesthesia, with gastroscopy, preliminary to laparotomy. Again, there was always danger of damage to the esophagus and stomach (particularly the latter in ulcer or cancer), and, furthermore, it was possible by this means to explore only a relatively small portion of the stomach. The writers of the paper invariably resorted to *x*-ray examination by a competent röntgenologist before operation; but while, unquestionably, much information could he thus secured, the radiograph would not always show the lesion, and the interpretations of even the most skilled specialists in this department were not invariably correct. In the course of their experimental investigations the authors had found that a gastric ulcer, of even considerable size, might be so covered hy the folds of the mucosa that it was impossible to see it through the gastroscope unless the stomach was inflated. Diculafoy had demonstrated that even on autopsy it had proved difficult to detect superficial ulcer when it lay concealed in some of these folds. This would suggest, further, the value of the inflating gastroscope for locating a hemorrhagic lesion requiring suture. Closure of the transverse duodenum, which had been observed to occur during the experiments, Dr. Kemp believed to be due to pressure of the distended stomach, torsion by the muscle of Treitz, and the downward pull of the mesenteric vessels, combined. Complete distention of the stomach and duodenum therefore took place before the cardiac orifice of the stomach opened. These facts explained the possibility of artificial gastric distention. The direct pneumatic gastroscope might be of service in the following ways: (1) In determining the character and position of an ulcer; (2) in determining the number of ulcers or erosions, and hence the amount of resection of the stomach required; (3) in determining the position of a foreign body and facilitating its removal; (4) in the study of the pylorus; (5) in revealing the point of an intragastric hemorrhage, and thus rendering rapid ligation possible; (6) in facilitating the removal of a polypus. Moreover, by its aid a scraping from an ulcerated surface might be secured, and a study made of the bacterial types found in gastric or duodenal ulcers with a view to determining the etiology. A small section of tissue could also be obtained for examination. The paper contained detailed reports of the authors' experimental investigations, which involved much careful research. Some of these (in which they received valuable assistance from Dr. E. E. Smith) were for the purpose of finding the best means for sterilizing the instrument. A considerable number of experiments were performed on dogs and on the cadaver. Incidentally, Dr. Kemp stated that he always had the patient prepared for operation upon the stomach as follows: 1. Hexamethylenamine, 5 grains three times a day, to disinfect the genito-urinary tract. 2. Sodium bicarbonate, 20 grains three times a day, to prevent acidosis. 3. No solid food, no milk, for twenty-four hours previous to operation. All food liquid, strained and sterile; mouth washed with acetozone 1/1,000, or other efficient mouth wash; also gargle. 4. Half an hour before operation (before starting the anesthetic) thorough lavage of the stomach with acetozone, 1/1000, or with sterile normal saline solution. All fluid completely aspirated from the stomach, so that the surgeon may have a clean and dry field. By this method, he said, the stomach was certainly freed from some of its bacteria, and nourishment could be given nearly up to the hour of operation; often a matter of importance. As most of these patients were sufferers from motor insufficiency, lavage as a preliminary to operation was imperative. At the conclusion of the paper Dr. Kemp demonstrated the use of the gastroscope on the body of a dog recently killed.

Dr. E. E. SMITH said that he had been impressed by two phases of this invention: first, its adaptability to the purposes for which it was intended, and, second, the great practical value of which it seemed likely to prove. In regard to the experiments which had been made for the sterilization of the instrument, it was a fact that 80 per cent. alcohol was a more efficient antiseptic than the stronger 95 per cent. alcohol. The diluted alcohol was of more value in this respect just as heat in the presence of moisture was more efficient than dry heat. It was as yet too early to say to just what extent the instrument would prove of service. Thus, it was perhaps a question what the importance was of an ulcer of such a character that it escaped detection by other means. In one way, however, the inflating gastroscope might possibly prove of great value. From recent investigations it seemed probable that before very long we would be able to make an early diagnosis of carcinoma from the blood, and then if by this means the location of the lesion could be determined in the beginning, it would certainly be a great point gained.

Dr. WILLIAM P. HEALY said that he had had that day a case in which he hoped to have made trial of the new instrument, but had found that it was not one calling for its use. To just what extent it would prove a useful addition to our present clinical resources it was impossible to say at present. Of course, if, after opening the abdomen, we found extra-gastric signs, there would be no need of further information. He was sure, however, that every surgeon of experience had had cases in which the symptoms pointed to some lesion of the stomach, yet the gross inspection revealed none. Now, if we were to make an exploratory incision in the stomach, and examine its interior by means of this instrument, we would be in a position

to know positively whether or not a gastric lesion was present. He thought that in most instances it would be necessary to make an anterior incision, as it seemed to him that it would be very difficult to make use of a posterior gastroenterostomy incision for the exploration. It would appear, therefore, that the field of usefulness of the inflating gastroscope was a somewhat limited one, though in a certain kind of cases it was likely to prove of great service. He would like to inquire why the instrument could not be made smaller; thereby increasing its availability. Again, there were some kinds of things which could not be sterilized. Thus, the wires would have to be covered with towels, and it seemed to him that it would be necessary to have some one to look exclusively after such matters.

Dr. SINCLAIR TOUSEY said that his own experience, like that of Dr. Kemp, went to show that *x*-ray findings should not alone be relied upon for a diagnosis in many cases of gastrointestinal disease. In numerous instances he had found the history and symptomatology of the greatest assistance. After all, the *x*-ray did not show us the stomach or intestine, but simply the size, shape and position of a bismuth meal or enema at a certain time after its administration. Some few departures from the normal appearances were, indeed, pathognomonic, and from the radiograph in such a case the history and symptoms might be deduced with accuracy; but there were many instances in which two or more conditions would produce a similar *x*-ray appearance, and the symptoms and history—and sometimes an exploratory operation—were necessary to a diagnosis.

Dr. ROBERT T. MORRIS said that this instrument of precision was a distinct addition to our means of diagnosis. Among the conditions in which he believed it would be of great service were, bloody-sponge ulcer, which was not benefited by gastroenterostomy, multiple ulcers, and indurated ulcer. In the last of these we could not always tell just where the active crater was situated, and the gastroscope would at once determine this. When an active ulcer was found we should not wait to ascertain whether we had to deal with cancer or not, but should take it out promptly. Again, linear ulcers near the pylorus had always been difficult to diagnosticate, and here also the instrument would prove of value. An important field of its usefulness would be the exact locating of foreign bodies; thus rendering their extraction a simple matter. As to the anterior incision, some German surgeons now thought it best to make this first.

Dr. ANTHONY BASSLER said he had a dim recollection that a year or two ago he had seen the account of some one examining the interior of the stomach by means of an endoscope. While he had no desire whatever to detract from the value of Dr. Kemp's work, the question had occurred to him whether, in cases where gastroenterostomy was done, it would be wise to risk the possible loosening of the clamp which might attend the introduction of the gastroscope. He would like to know whether, even with perfect technique, there would not be great danger of giving rise to sepsis. After the suturing, also, it seemed to him that there would remain the danger of some leakage. Still further, might not the inflation itself of the stomach be attended with more or less danger?

Dr. EDWARD WALLACE LEE said it seemed to him that Dr. Bassler was something of a pessimist, and that he had exaggerated the danger of producing a septic condition. As a matter of fact, the peritoneum was really very tolerant. He had known of perforation of the stomach to occur, with emptying out of the entire gastric contents, and yet it had been possible to clean up the peritoneal cavity without any untoward results whatever.

Dr. KEMP, in closing, said that it was a perfectly easy matter to have the instrument of smaller diameter. The reason why he had had it made of the present size was because with a smaller diameter so good a light could not be obtained. The larger instrument was therefore preferable. He wished to have it understood, however, that the gastroscope was as yet in the experimental stage. As to sterilization, he believed that with the precautions which he had inculcated there was little or no risk of sepsis, and he saw no objection to Dr. Healy's suggestion that there should be a special person to look after the technique. In gastric operations at which he had been present, at which proper preliminary precautions had been taken, he had never seen a single drop of material escape from the stomach. This was a matter which depended entirely upon the preparation of the patient beforehand, especially the use of thorough lavage with aspiration just before operation. In reply to Dr. Bassler he would say that the position of the patient was of great importance. The proper position was the reverse of the Trendelenburg. He did not think there was any danger of post-operative dilatation. The inflation of the stomach was done rather rapidly, the entire period of examination consuming very little time, and cathartics were given on the table or immediately after the patient had been put to bed. As to Dr. Bassler's having seen some notice of a previous attempt to inspect the interior of the stomach through a gastric incision, this was no doubt the one to which reference had been made in the paper. Rovsing and Gallant had used a cystoscope for this purpose, and their procedures were the only things of the kind he had been able to find in all medical literature. He believed that with the instrument demonstrated this evening and with the proper technique, such as had been described, the surgeon would secure valuable information in some cases. For removal of a foreign body the method was ideal.

**Tuberculosis Following Typhoid Fever.**—Dr. CHARLES E. WOODRUFF, Lieutenant-Colonel (retired), Medical Corps, U. S. Army, in this paper, said that Ralph and Matson, of Portland, Oregon, were probably the first to notice that typhoid fever appeared with great frequency in the previous histories of consumptives, and in their history blanks it now headed the list of predisposing causes. The long interval which might elapse between the beginning of tuberculosis activity and the onset of symptoms generally prevented the discovery of the activating cause. It was not strange, therefore, that the literature should be so devoid of studies of the relation between typhoid and tuberculosis. Nevertheless, there was a decided impression prevalent that any serious infection may lead to consumption. The matter had assumed great importance since the recent discovery that every child is born free of tuberculosis, but soon acquires it, and that in every one of us the lesions become active sooner or later. By personal inquiries, both here and in Europe, he had found that these facts were now accepted as established. It was probable, then, that all civilized people were tuberculous and undergoing constant auto-vaccination, causing an effective immunity. Phthisiographers the world over seemed to be coming to the opinion that no one is ever infected in adult life, and that if incipient tuberculosis does develop in an individual, it is because something has interfered with the manufacture of his antibodies. Hence, the new viewpoint was that such infections as measles, whooping cough, and typhoid fever do not render us susceptible to tuberculous invasion, but reduce our resistance to the bacilli, which are already intrenched in the system. The earlier in life we received any infection, the more likely it was to cause the tuberculosis to spread; tubercles being found in the majority of children dying of any disease. All this had long ago been pointed out by Laennec, and there were now not a few who stated that not only tuberculous glands, but tubercles elsewhere, could be found post-mortem in every child over six, if we looked for them. As we grew older, and acquired full immunity, the fewer of us became actively tuberculous after the other infections, and probably the only persons who became actively tuberculous after typhoid were those who had partially lost their immunity through some other causes. It seemed that typhoid would cause general tuberculosis in all those whose lesions were active, and that it would activate a certain proportion of quiescent cases, in which symptoms developed after a period varying with their original resistance. At present, active tuberculosis was far less common than formerly, and there must be fewer cases of tuberculosis following typhoid, either directly or remotely. It might be mentioned here that the three diseases which seemed to be most frequently followed by tuberculosis of the lungs—measles, whooping cough, and typhoid—were all complicated with bronchitis. When one was losing his immunity to tuberculosis through overwork, lack of nutrition or fresh air, or from any other cause, there came a time when his latent lesions were just able to spread; the system being so delicately balanced that a straw would affect it one way or the other. Le Tulle, of Paris, had found that all serums and vaccines would cause incipient cases to grow rapidly worse, and had particularly noticed this in the case of diphtheria and tetanus antitoxins. Certain observers here and abroad had found that antityphoid vaccine brings

out any latent or chronic disease, particularly tuberculosis, and Combe, of Paris, stated that the vaccine acts like tuberculin. There was ample justification for suspecting that a fever which attacked a person in apparent health, which cleared up in a few weeks, and which later was followed by tuberculosis, was some non-tuberculous infection such as typhoid or malaria; while a fever which attacked a person in poor health, and the course of which was typhoidal, though atypical, was probably a mere run of fever incidental to incipient tuberculosis. Consumptives seemed to have had more typhoid fever than the rest of the population, though there was no way of determining this point accurately. The speaker gave a number of statistics indicating that such was probably the case, and went on to say that it was safe to estimate that in Great Britain 1 per cent. of the population was in a condition to get rapid consumption should they become infected with typhoid fever, and in this country, 2 per cent., or even more. There were other facts which, taken together, showed a relation between typhoid and tuberculosis, though each by itself was of little value. For instance, the mortality curve of tuberculosis, which rose rapidly from childhood, reached its maximum before thirty and declined after thirty-four, while the maximum in the curve of typhoid was reached at fifteen and declined after twenty-five. The curve of tuberculosis seemed to follow that of typhoid after an interval of about nine years, and the average length of life after tuberculosis became active was said to be seven years. This might mean, therefore, that the typhoid, mostly contracted before twenty-five or thirty, had been partly responsible for raising the maximum mortality from tuberculosis nine years later. Again, it was significant of the relation of typhoid to tuberculosis that males predominate in the deaths from both causes. Furthermore, where typhoid fever was prevalent there should be more tuberculosis than in places free from typhoid, and variations in the typhoid deathrate should be followed by similar variations in the tuberculosis deaths there.

It was also evident that in a place where tuberculosis was quite common typhoid should have more effect in increasing the deathrate from tuberculosis than in places having little tuberculosis. These propositions seemed to be proved by a series of charts which he had found in the Office International d'Hygiéne Publique in Paris, in which it was noticeable that the two curves showed more or less parallelism throughout the civilized world. On the charts were also given the curves for other infections—smallpox, diphtheria, scarlet fever, and plague; but these came in epidemics, and presented irregularities having no apparent relation to the two endemic diseases typhoid and tuberculosis. Unfortunately, neither measles nor whooping cough had been considered of sufficient importance to record, and we had no means of determining how far they were responsible for irregularities in the curves. As these diseases appeared to be as common as they ever were, they had not influenced the tuberculosis curve, except, perhaps, to keep it up. It was exceedingly difficult to calculate how much reduction of tuberculosis there should be for a reduction of every 100 cases of typhoid, but as far as could be estimated from the information available it seemed fair to judge that for every five lives saved from typhoid death, there would be a reduction of two or three in the tuberculosis deaths. Now, the curves showed that for every reduction of five deaths by typhoid there were more than three lives saved from death by tuberculosis in the time covered by the charts. In England there had been a reduction of 22 or 23, and in Germany about 35, or more, though in France, where infections were still high, there was little reduction in tuberculosis, and in Italy only about 4. In the United States it was about 35. These differences could be accounted for by the coincident reduction by modern sanitation and therapy of the numerous factors causing active tuberculosis. Karl Pearson, the eminent statistician, warned against drawing conclusions from parallel curves, as it not infrequently happened that there were two independent causes at work, one for each set of facts, and wholly unrelated; but in view of the evidence that typhoid is frequently followed by tuberculosis, there could not be any reasonable doubt that the reduction of typhoid was responsible for a good share of the modern reduction of tuberculosis. Where the other infections were high, as in France, tuberculosis was still common, but where public health measures were effective the drop in tuberculosis was amazing. As a rule, the higher the typhoid rate, the nearer did the two classes of deaths approximate. As time progressed typhoid ceased to be a cause of tuberculosis activity. One of the most remarkable instances of the reduction of tuberculosis by reducing typhoid was in the British army. All other armies showed a similar reduction, but not nearly to such an extent, because none of them had been burdened so long with such a typhoid mortality as had afflicted the 70,000 troops in India until modern sanitation was applied. Antityphoid vaccines had had little or nothing to do with the first two-thirds of this improvement, and in 1910 only about 60 per cent. were protected; yet for 1911 the typhoid was reduced to 1.7 per 1,000. The tuberculosis admissions showed equally astonishing reductions. After 1903 tuberculosis declined at nearly the same rate as the typhoid, until a minimum was reached in 1907-8. Then came a 70 per cent. rise, coincident with the large number of inoculations, and later a slight decline, in 1910 and 1911, corresponding with such reduction of typhoid as would have been occasioned by continued improvement in sanitation. In the United States Army also the same dependence of tuberculosis upon typhoid was seen after 1890, when, as in civil life, bacterial diagnosis became more common; but after typhoid vaccines were widely used tuberculosis ceased to decline with the typhoid. The health authorities of both New York and Pennsylvania had reported that in recent years in their respective states both typhoid and tuberculosis had markedly declined, and at about the same rate. The Spanish-American War had added to the deaths in many cities in 1898-9, and the disasters of this war and those of the campaign against the Boers had stirred up the world to inaugurate an antityphoid crusade which showed immediate results.

Having shown tables for various cities of this country and Europe, taken in groups of five years, Colonel Woodruff said there was no exception to the rule that a decrease of typhoid is accompanied by a decrease of tuberculosis. Incidentally, he referred to the fact that Prendergast, of Brooklyn, had used typhoid vaccine in four cases of diabetes, because he had seen it stated that in diabetics sugar disappeared from the urine during typhoid fever. Two of his patients promptly became consumptive, and one of these died (probably from gangrene) nine days after a dose of 50,000,000 which was given eight days after tubercle bacilli were found in the sputum (MEDICAL RECORD, January 3, 1914.) In concluding, the speaker said that in practical therapy it would be wise to treat typhoid patients as though they were tuberculous; indeed, at all events, they did better if liberally fed and kept in cool or cold air.

Dr. ROBERT COLEMAN KEMP said Col. Woodruff certainly deserved great credit for the vast amount of research of which his paper gave evidence. The subject was a difficult one to discuss, however, as so little had been previously known regarding it. His contention that a very large proportion of the human race had at some time been infected with tuberculosis, as shown by autopsy, he believed to be correct. Curiously enough, it had been reported abroad that of all cases coming to autopsy, from 5 per cent. to 10 per cent. gave evidence of an old gastric ulcer, although no symptoms indicating this might have been noted during life. While tuberculosis was many times more frequent than gastric ulcer, it was well known that prolonged chronic ulcer might have tuberculosis as a sequel; lowered resistance being no doubt a factor in this result. It seemed entirely reasonable that tuberculosis should follow typhoid fever. We knew that post-typhoid colitis, often ulcerative, might continue for months, and it seemed to him that there was no reason why the tubercle bacillus might not enter by this route as well as by the lungs. The similarity between the curves of typhoid and tuberculosis which had been shown was interesting and somewhat significant, and he had been particularly struck by the fact that while the percentage of cases of typhoid rapidly diminished after antityphoid vaccination, there was rather an increase in those of tuberculosis. It was a recognized fact that serums and vaccines would at times activate some pre-existing pathological process. In certain asthmatic conditions, for example, the use of diphtheria antitoxin might set up even dangerous symptoms. Some years ago he had treated a young man affected with lymphatic enlargements, believed to be of pseudoleukemic nature. These ultimately disappeared, but within the past few weeks the patient had contracted diphtheria, and while the diphtheria rapidly cleared up as the re-

sult of the administration of 15,000 units of antitoxin, the injection was immediately followed by a recurrence of the glandular enlargements. The speaker said he believed that antityphoid vaccines were useful, but that those to be vaccinated should first be carefully examined. Typhoid and antityphoid vaccines, in his opinion, might in some instances activate a latent tuberculosis. Although antityphoid vaccination was an excellent thing, and ought, no doubt, to be more frequently employed, it seemed to him absurd that enthusiastic advocates of such vaccination should claim that deleterious effects were impossible. The more we studied the effects of serums and vaccines, the more would we be convinced of the error of such a view. Regarding high caloric feeding in typhoid and tuberculosis, Dr. Kemp said he thought this was now overdone. A typhoid patient should be given from 2,000 to 3,000 calories, or a little more if no tympanites resulted and the food were digested; but no person, whether tuberculous or suffering from typhoid fever, with diseased kidneys, with derangement of all the digestive organs, and with a temperature of 103° or more, could digest twice the amount of food which he would in health.

Dr. Francis A. Prendergast said he thought the author of the paper laid too much stress on typhoid as a cause of tuberculosis, to the neglect of other causes and factors, and that in many places his figures failed to support his theory. There was a very large class of patients who had partially recovered from tuberculosis and were in a condition for something or other to reduce their vitality and give their latent disease an opportunity to flare up. In the army and navy the men, while sons of Mars, were much given also to the worship of Bacchus and Venus, and alcoholism and venereal disease were very prone to thus reduce vitality and afford a latent tuberculosis its chance to light up. It was a fact, and one much emphasized by Osler, that miliary tuberculosis was often diagnosticated as typhoid fever, and many cases were put down as tuberculosis following typhoid, when, in reality, the tuberculosis was present from the start, and no typhoid had ever existed. In 1911 the speaker had brought to the attention of the profession a new skin reaction test for typhoid fever (Medical Record, December 31, 1911); and this test might help in a differential diagnosis, as it was not operative in any of the diseases giving a positive Widal reaction—severe anemias, cancer cachexia, and miliary tuberculosis. In the two cases of diabetes cited by Dr. Woodruff in which he (Dr. Prendergast) had employed typhoid vaccine in small doses in an attempt to control the output of sugar (Medical Record, January 3, 1914) he felt sure that the tuberculosis did not develop from the use of the vaccine. In almost any textbook would be found the statement that tuberculosis was very common in diabetics, and these, he believed, were only additional instances of lowered resistance lighting up a latent tuberculosis. Typhoid vaccine was contraindicated in all acute diseases, alcoholism, and most chronic diseases. He had never had any bad results from the employment of the vaccine in normal subjects. He could heartily endorse Dr. Woodruff's treatment of typhoid fever by means of fresh air and feeding. The diet he was accustomed to employ yielded about 2,900 calories. In the light of our present knowledge, the use of an exclusive milk diet in this disease he thought should be condemned.

Major F. F. Russell, Medical Corps, U. S. Army, said that it was always dangerous to draw conclusions from parallel curves, and such curves, unless accompanied by certain data, were very difficult to interpret correctly. As to antityphoid vaccine in the army, this was now the beginning of the sixth year in which it had been employed. During the past three years, in which the number of troops varied between 75,000 and 90,000, it had been compulsory, and if the contention were true that such vaccination activated tuberculosis, there should have been some increase in the amount of tuberculosis. As a matter of fact, however, for the past five years there had been a steady decrease in the disease, and not an increase. It did not follow, therefore, that antityphoid vaccination would light up tuberculosis, and he was convinced that in healthy young men there was no danger whatever of its activating the disease. The rule was strictly observed in the army to vaccinate only the healthy. The records published in the annual reports of the Surgeon General of the Army afforded a complete refutation of the theory set forth in the paper, so far as it concerned antityphoid vaccination.

## PRACTITIONER'S SOCIETY OF NEW YORK.

*Two Hundred and Sixtieth Regular Meeting, Held February 6, 1914.*

Dr. John W. Brannan in the Chair.

**A Method of Plicating Voluminous Ceca.**—Dr. Joseph A. Blake read this paper. (See page 599.)

Dr. C. L. Gibson said that he was very much impressed by Dr. Blake's ideas on the subject ever since their presentation at a surgical gathering some time ago. Unfortunately, however, he had not had any cases since that time in which the operation suggested by Dr. Blake was suitable. He thought that the procedure suggested was eminently logical and would not hesitate to use it at the first opportunity.

Dr. F. S. Meara said that in the medical mind grave doubts had been raised by the advocacy of total resection of the colon by some surgeons, especially by those who were followers of Mr. Lane. He said that *x*-ray studies showed that the products of digestion traverse the distance between the stomach and the distal end of the small intestine in about two and one-half hours; on the other hand they remained in the large intestine any time between twenty-four and forty-eight hours. It would seem to him that the elimination of the large intestine or of a greater portion of it would prove very serious so far as the absorption of food was concerned. On the other hand voluminus ceca were a real and troublesome condition, and the procedure suggested by Dr. Blake appeared to him as much more in accordance with physiology than the more radical operations. The operation suggested retained the absorbing surface of the intestine, yet did away with the mechanical difficulties and stasis occasioned by the dilated portion.

Dr. Blake said that Dr. Meara's words opened a very large question in physiology and surgery. The best method of dealing with a very large or dilated colon had not yet been discovered. He personally thought that the symptoms ascribed to such conditions were very real. They were occasioned by stasis, decomposition, with the formation of toxic substances and sometimes inflammation. His experience with the resection of large portions of the colon for carcinoma, had led him to believe that in the presence of dilatation the removal of a portion of the large intestine might be very beneficial. In carcinoma, of course, the operation was a matter of necessity, but he had little doubt of its efficacy for the condition under consideration. His paper to-night, however, was confined to a much smaller subject, namely, to the proper treatment of voluminous ceca alone; this condition presented itself quite frequently, and the results obtained by the method outlined seemed encouraging enough to justify its presentation. Dr. Blake was anxious to call attention to the frequency with which weakened abdominal muscles accompanied or perhaps were even responsible for the dilatation of the intestines. Such muscles did not produce sufficient intraabdominal pressure, thus causing stagnation in the portal circulation and atony of the intestinal muscularis. Anything tending to increase the laxity of the abdominal walls, such as frequent pregnancies or abdominal operations were common etiological factors. This fact in itself was a strong contraindication to operative treatment of such cases. The neurasthenic state accompanying these conditions was both cause and effect; the intestinal intoxication producing both physical and psychical effects and the psychical condition leading to an improper mode of life. As to the treatment, while abdominal supports helped they did not produce the same effects upon the intraabdominal vessels as was produced by actively contracting abdominal muscles. The best results should, therefore, be obtained by proper exercises; and in practice, this method had produced the most beneficial results. Only in the most exaggerated instances of enlarged and flaccid colons should operative treatment be advised.

**Lumière Plates of Pathological Conditions.**—Dr. C. L. Gibson showed these plates. He said that he had recently, with the help of Dr. Beekman, endeavored to preserve a record of the more interesting cases of his surgical material by taking Lumière photographs of some cases as well as of pathological preparations. These photographs, as is well known, rendered not only the form but the color of the material as well. He had had variable success and this evening showed a number of plates, some fair and some very good.

The subjects illustrated were as follows: A patient suffering from melanosarcoma; his skin showing a very curious bluish brown discoloration; a tubercular rash; specimens of enchondroma as well as the tumor as it appeared in the living subject; acute hemorrhagic pancreatitis; subcoracoid dislocation of the humerus; several cases and specimens of carcinoma of the breast; fibroma of the leg; Charcot joint; a case of inguinal hernia; a case of psoas abscess; tuberculosis of the foot; a case of yaws; calculous pyonephrosis; contracture of the arm following a burn; hypertrophy of the breast in a male child; Buerger's disease or thrombophlebitis obliterans; ruptured spleen removed by operation in the course of typhoid fever, from a case, the details of which were communicated to the society by Drs. Conner and Downes at a previous meeting; subdeltoid bursitis; supernumerary nipple in the male; a large spleen from a case of splenomegaly; a fibroid uterus; specimens of fatty degeneration and of tuberculosis of the kidney; fibroma of the breast; epulis; specimens of double cystic ovary and double pyosalpinx; a gall-bladder filled with gallstones; prolapse of the uterus; and a specimen of hypertrophied prostate.

Dr. Blake said that the pictures gave a very good general idea of the lesions, but lacked detail. He was much interested in the case of thrombophlebitis shown. This affection was seen quite frequently in the material of the Vanderbilt Clinic. He said that treatment by baking as suggested by Dr. Gibson had to be employed with caution as there was no circulation to take away and distribute the heat applied and damage could be easily done. Most of the cases he had seen were in Hebrews who were smokers of cigarettes. He had seen one American of Anglo-Saxon parentage who had the disease. In answer to a question of Dr. Brannan's Dr. Blake said that he could see no rationale in the operation of anastomozing the vein and artery in these cases.

Dr. Gibson said that he agreed with Dr. Blake in his estimate of the operation discussed. The danger of baking did not occur to him, but, as a matter of fact, the patient under discussion was not harmed by the treatment.

Dr. Meara said that he was interested in the statement that the disease was confined to Hebrews alone. He had seen a case of thrombophlebitis in which amputation was necessary, in a person of a different race. Whether the lesion was of the same nature he was not prepared to state.

Dr. Beekman said that the pictures shown were in the nature of first attempts with Lumière plates and he hoped to be able to produce better results in the future. The difficulty lay in the time necessary for exposure; while this was counted in seconds in ordinary photography, it took minutes with Lumière plates and of course it was very difficult to insure perfect quiet in the subjects and thus obviate distortion. That was the reason why they had better success with pathological specimens than with the living subject. This difficulty, however, could be obviated by the use of flashlight, the quantity of powder used being quite accurately determined for each case. He thought that as soon as he was enabled to use flashlight in the wards of the hospital or have special facilities the pictures would gain clearness and definition.

### Pathological Society of Philadelphia.

At a stated meeting held March 12 at the Henry Phipps Institute of the University of Pennsylvania Dr. Robert N. Willson, Jr., presented specimens from "A Case of Ulcerative Endocarditis." The patient was an alcoholic who developed pneumonia in conjunction with preexisting symptoms of valvular disease of the heart and atherosclerosis. At autopsy the mitral valve ring was found the seat of marked calcareous deposit, and in one situation there was an extensive and deep-seated ulcerative process. The aortic leaflets were uninvolved. One of the kidneys was enlarged and inflamed, while the other was of the infantile type. The liver was cirrhotic. Dr. Willson presented also a heart exhibiting "Vegetative Endocarditis Involving the Aortic Leaflets."

Dr. G. L. Kite presented a communication entitled "Effect of the Ligation of the Pulmonary Vein of the Rabbit." In addition to hyperemia of the affected portion of lung there occurred an exudate into the alveoli marked by the presence of large numbers of mononuclear leucocytes.

Drs. Karl F. Meyer and Paul A. Lewis presented a communication entitled "Some Observations on the Latency of *Bacillus tuberculosis*." In connection with the treatment of tuberculosis in cattle with attenuated cultures of tubercle bacilli from another source it was found experimentally that such bacilli might reside within the bodies, in the lymph-nodes, of the host for many months and even more than a year without giving rise to active manifestations.

Drs. C. M. Montgomery and Paul A. Lewis presented a paper entitled "Some Observations of Artificial Pneumothorax." They pointed out the purposes to be gained from the procedure mentioned and the dangers attending its establishment, together with the anatomical conditions present in several cases in which a fatal result ensued.

Dr. Paul A. Lewis presented a communication entitled "Some Modifications of the Tubercle Bacillus." He pointed out that this microorganism is capable of undergoing marked changes in virulence, so that one must be extremely careful in the employment of living cultures of any form of tubercle bacilli in the treatment of tuberculosis.

Dr. Paul A. Lewis also presented a communication entitled "The Basis for Chemotherapeutic Experimentation in Tuberculosis." He reported observations showing favorable effects from the use of trypan-red in combination with iodine in the treatment of tuberculosis of the rabbit's cornea.

Dr. G. L. Kite discussed "Methods of Microdissection." He showed how, with the aid of the compound microscope and the employment of a special stage, a special condensing mechanism, and a specially devised glass needle, it was possible to study with the utmost detail the fine structure of cells. It was found among other things that the living cell was not constituted of a reticulum containing fluid within its interstices, but that it was made up of gelatinous substance that could be displaced and divided for purposes of dissection and minute study.

## State Medical Licensing Boards.

### STATE BOARD EXAMINATION QUESTIONS.

#### Kentucky State Board of Medical Examiners.

*December* 11-13, 1913.

ANATOMY.

1. Give changes of, and bones involved, in flat-foot.
2. Give anatomical reasons for Pott's fracture.
3. Give the origin and distribution of the ovarian arteries.
4. (*a*) Describe the femoral artery; (*b*) name its branches and their distribution.
5. Describe Hunter's canal.
6. Name and classify the spinal nerves.
7. Describe the lumbar plexus.
8. Locate and give detailed description of the gall-bladder.
9. Name and describe the ligaments of the bladder.
10. Give structure and blood supply of the uterus.

PHYSIOLOGY.

1. Give function of portal circulation.
2. Describe the interchange of gases in the lungs.
3. Describe and give functions of gastric juice.
4. Describe the process of skin desquamation.
5. Discuss (*a*) an afferent nerve, (*b*) an efferent nerve.
6. Discuss the fluids of reproduction from a physiological standpoint.
7. What is the function of the medulla oblongata?
8. Give (*a*) relative number and (*b*) function of red and white blood corpuscles.
9. Why is the lymphatic system so essential to the human body?
10. Discuss an uriniferous tubule from a physiological standpoint.

CHEMISTRY.

1. What is the function of oxygen in the body?
2. (*a*) Give formula of common baking soda and common salt. (*b*) What effect, if any, has each upon digestion?
3. Define and give example of (*a*) an acid, (*b*) base, and (*c*) salt.
4. What is meant by specific gravity, and of what

value is it in uranalysis? Give normal specific gravity of urine.

5. Define (*a*) ozone, (*b*) chemical affinity, (*c*) reagent, (*d*) volatile, and (*e*) ferment.

6. Give in full a reliable test for (*a*) albumin in urine; (*b*) pus.

7. Give symptoms of arsenic, strychnine, and morphine poisoning. Give antidote for each.

8. What are the most common constituents of urinary calculus?

9. What significance has the presence of sugar in urine? Indican?

10. (*a*) Approximately how many elements are there? (*b*) Name five of the most common found in the human body.

ETIOLOGY AND PHYSICAL DIAGNOSIS.

1. Give etiology and physical signs of three forms of organic heart disease.

2. Differentiate lobar and bronchial pneumonia.

3. How would you differentiate (*a*) renal calculus, (*b*) appendicitis, and (*c*) gallstones.

4. Give etiology and differential diagnosis of (*a*) carcinoma, (*b*) sarcoma, and (*c*) lupus.

5. Give differential diagnosis of (*a*) acute alcoholism, (*b*) cerebral hemorrhage, and (*c*) opium poisoning.

6. Give (*a*) etiology and (*b*) diagnosis of hip-joint disease.

7. Give etiology and differential diagnosis of typhoid fever and acute gastritis.

8. Differentiate extrauterine pregnancy from chronic salpingitis.

9. Give etiology and differential diagnosis of chronic parenchymatous and interstitial nephritis.

10. Give etiology and differential diagnosis of gastric ulcer, gastric carcinoma, and gastralgia.

## ANSWERS.

ANATOMY.

1. *Flat-foot:* Ordinarily the sole of the foot does not rest on the ground; the points of contact are the os calcis, the head of the first metatarsal bone, and the head of the fifth metatarsal bone. But in *flat-foot* the arch breaks down, the entire plantar surface rests on the ground, the ligaments are overstretched, the concavity on the inner side of the foot disappears, and the foot appears longer and broader; the patient walks on the inner side of the foot, and the foot is everted and abducted.

2. *Potts' fracture* is caused by a twisting or forcible eversion of the foot; the internal lateral ligament is severely stretched and is either ruptured or else it tears off the internal malleolus; the external malleolus is forced outward, and the fibula breaks at its weakest point, namely, just above the malleolus.

3. The *ovarian arteries* arise from the abdominal aorta, and are distributed to the ovaries; branches also go to the ureters, Fallopian tubes, broad ligament, and to the uterus (through anastomosis with the uterine artery).

4. The *femoral artery* is the direct continuation of the external iliac; it begins behind Poupart's ligament, passes down the front and inner part of the thigh through Scarpa's triangle, and teminates at the opening in the adductor magnus, where it becomes the popliteal artery. Its *branches* are: Superficial epigastric, superficial circumflex iliac, superficial external pudic, deep external pudic, profunda femoris, muscular, and anastomotica magna. By means of these various branches it *is distributed to:* Superficial inguinal glands, skin, and superficial fascia of the inguinal region, penis and scrotum (or labia majora), perineum, flexor muscles on the back of the thigh, the adductor muscles of the femur.

5. *Hunter's canal* is situated in the middle third of the thigh, extending from the apex of Scarpa's triangle to the opening in the adductor magnus muscle. It is covered over by an aponeurosis which extends from the vastus internus to the adductor longus and magnus, and contains the femoral artery, femoral vein, and internal saphenous nerve. Externally, the canal is bounded by the vastus internus; and internally by the adductor longus and magnus.

6. There are thirty-one pairs of spinal nerves, which are classified as follows: Cervical, 8 pairs; thoracic, 12 pairs; lumbar, 5 pairs; sacral, 5 pairs, and coccygeal, 1 pair.

7. The *lumbar plexus* is situated in the psoas muscle, and consists of branches of communication between the anterior division of the four upper lumbar nerves. The arrangement of the plexus is quite variable. The branches are: Iliohypogastric, ilioinguinal, anterior-crural, genitocrural, cutaneous, obturator, and accessory obturator.

8. THE GALL-BLADDER AND BILE-DUCTS.—The *gall-bladder* is a conical bag placed in a fossa on the under surface of the right lobe of the liver. Its upper surface is attached to the liver, and its fundus and posterior surfaces are invested by peritoneum reflected from the adjacent surface of the liver. The body is in relation in front with the liver, and behind with the first part of the duodenum, the pylorus, and the hepatic flexure of colon. The fundus is in contact with the parietes opposite the ninth right costal cartilage. It is about four inches long, and holds about one ounce. Its duct passes from the neck of the gall-bladder downward, backward, and to the left to join the hepatic duct.

9. *Ligaments of the bladder.*—There are five true ligaments, and five false ligaments. The *true ligaments* are: Two anterior ligaments, which extend from the back of the pubic bone to the front of the neck of the bladder; two lateral ligaments, derived from the pelvic fascia; and the branches, extending from the summit of the bladder to the umbilicus. The *false ligaments* are: Two posterior ligaments extending from the posterior and lateral portion of the bladder to the rectum or uterus; two lateral ligaments, and the suspensory ligament. The false ligaments are all formed by folds of the peritoneum.

10. The *uterus* is composed of an external or serous coat, a middle or muscular coat, and an internal or mucous coat. The serous coat is derived from the peritoneum and covers the fundus and posterior surface; the anterior surface is covered as far as the junction of the cervix with the body. The muscular coat forms the bulk of the uterus, and is arranged in three layers, an outer, middle, and inner. The mucous membrane is adherent to the muscular coat, it lines the uterus throughout, and is continuous with the lining of the vagina and also with the Fallopian tubes and peritoneum. The *arteries* supplying the uterus are the uterine and ovarian.

PHYSIOLOGY.

1. The function of the portal circulation is to carry the venous blood from the stomach, intestines, pancreas and spleen to the liver. The blood thus carried is loaded with the products of absorption. In the liver this blood enters into close relation with the hepatic cells, and is finally carried to the inferior vena cava.

2. RESPIRATORY CHANGES IN THE LUNGS. *"Oxygen:* During a normal inspiration atmospheric air is drawn into the larger bronchi; here the tension of the oxygen is greater than the tension of that oxygen which is in the infundibula, where the oxygen tension in man has been calculated to be 13 per cent. of an atmosphere of oxygen. The gases in the infundibula, and consequently in the alveoli, are separated from the blood plasma in the lung capillaries by the flattened cubical epithelium of the alveoli and the endothelium lining the capillaries; it is believed that oxygen diffuses from the alveoli through the two kinds of epithelium into the plasma of the venous blood which has just arrived in the lung, and which is collected in the distended capillaries. Now, oxygen accumulates in the blood, which is consequently becoming rapidly arterial, until its tension rises to 38.5. It is obvious, therefore, that there must be another factor at work besides diffusion to account for this difference of oxygen tension. The epithelium which lines the alveoli is cuboidal in shape, and was originally derived from the epithelium lining the alimentary canal, and in function it is probably secretory. The inference to be drawn, therefore, is that some oxygen diffuses from the alveoli into the plasma of the lung capillaries so long as the oxygen in the alveoli is at a higher tension than that in the plasma; when, however, a state of equilibrium is reached, the cubical cells, possibly controlled by the vagi, begin to secrete oxygen from the alveoli into the blood plasma.

*"Carbon-dioxide* leaves the venous blood in the pulmonary capillaries and gets into the alveolar air, where its tension is usually 5 per cent. in males and 4.7 per cent. in women and children. The tension of carbon-dioxide in venous blood is higher than 5 per cent.; so that it is by diffusion that the $CO_2$ leaves the venous blood and enters the air in the alveoli, and it is by a

continuation of the process of diffusion that the $CO_2$ leaves the air in the alveoli and enters the bronchioles." (Lyle's *Physiology.*)

3. *Gastric juice* is a thin fluid, almost colorless, of acid reaction and taste, specific gravity varying from 1001 to 1006, and containing about 0.5 to 1.0 per cent. of solids. It contains pepsin, rennin, hydrochloric acid, mucin, salts, and water. Its main function is to dissolve proteids and change them into proteoses and peptones; it coagulates milk; it splits up fats; and it has some germicidal action.

4. *Skin desquamation:* "The deeper layer of the epidermis consists of cells which are polygonal in shape and moist in character, and is called the mucous layer or rete mucosum. The superficial cells are dry and flattened, and constitute the horny layer of the epidermis. There is a constant production of new cells in the epidermis taking the place of other cells, which are pushed toward the surface and finally shed by the skin. This process of shedding the superficial dry scales is constantly taking place, and is aided by the rubbing of the clothing against the skin and by the friction employed in bathing. The desquamation takes place in the form of minute scales. Only upon the scalp do they tend to become visible to the eye and appear as flakes, forming a condition commonly known as dandruff."—(*Personal Hygiene.*)

5. *Afferent nerves* carry impulses to the nerve centers. They are classified as: Sensory (general sensation), special sense nerves, thermic nerves, inhibitory, and excitoreflex nerves.

*Efferent nerves* carry impulses away from the nerve centers. They are classified as: Motor, vasomotor, trophic, secretory, accelerator, and inhibitory.

6. "The seminal fluid consists of secretions from the testes, vasa deferentia, vesiculæ seminales, prostate, Cowper's glands, and the muciparous glands of the urethra. It is whitish in color, viscid in consistency, alkaline in reaction, and possesses a characteristic odor. The amount ejaculated varies from 0.5 c.c. to 6 c.c. It contains from 82 to 90 per cent. of water, nuclein, protamine, proteids, xanthin, lecithin, cholesterin, fat, sodium and potassium chlorides, sulphates, and phosphates. From it may be obtained Charcot's crystals, which are a phosphate of the nitrogenous base, spermin, and which have their origin in the portion of the semen which is contributed by the prostate; to the decomposition of the substance which produces these crystals the odor of the semen is attributable. While the spermatozoa are the essential fertilizing agents the presence of the fluid portion of the semen is important as giving to them their mobility, without which they could not travel in the generative passages." (Raymond's *Physiology.*)

7. The *functions of the medulla oblongata* are: (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of coordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions; respiration, salivary secretion, mastication, sucking, deglutition, vomiting, voice, facial expression; it also contains the cardiac and vasomotor centers.

8. There are generally about 5,000,000 red corpuscles and about 7,000 to 10,000 white corpuscles to each cubic millimeter of blood. The ratio is therefore about one white to 500 or 600 red.

*Functions:* The *red blood cells* carry oxygen from the lungs to the tissues. The *white blood cells:* (1) Serve as a protection to the body from the incursions of pathogenic microorganisms; (2) take some part in the process of the coagulation of the blood; (3) aid in the absorption of fats and peptones from the intestine, and (4) help to maintain the proper proteid content of the blood plasma. The function of the *platelets* is not determined; it is possible that they take some part in the coagulation of the blood. The *plasma* conveys nutriment to the tissues; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys.

9. *Function of lymph:* (1) It conveys nutriment to all cells not directly reached by the blood; (2) in the intestines, it absorbs nutrient material (chiefly fat) and pours it into the blood stream for distribution; (3) it takes certain waste matters to the blood to be later eliminated by the lungs, kidneys, and skin.

Without the lymphatic system the above functions would be in abeyance.

10. "The Malpighian bodies and that portion of the urinary tubules known as the convoluted tubes are both engaged in the separation of the urine from the blood. The Malpighian bodies are probably engaged in secreting the greater part of the water of the urine, the process depending to some extent upon the pressure in the capillary tuft. The convoluted tubes are lined by glandular epithelium and are surrounded by a plexus of capillaries. The epithelium lining then appears to exercise a certain selective influence in secreting the urea, uric acid and pigment. These substances, having been separated from the blood and having entered the tubules, are washed down by the water coming from the glomeruli. While the secretion of the watery part of the urine takes place at the glomerulus the urea, uric acid, and other constituents are separated from the blood by the agency of the epithelium lining the convoluted tubes. Blood contains .02 per cent. of urea normally, while urine contains 2 per cent.; it is evident, then, that the epithelium of the kidneys is actively employed in selecting the urea in the blood and passing it into the urine."—(Ashby's *Treatise on Physiology.*)

CHEMISTRY.

1. The function of oxygen in the body is to support respiration and combustion.

2. *Baking soda* is monosodic carbonate, $NaHCO_3$. It is said to check the secretion of the gastric and pancreatic juices.

*Common salt* is sodium chloride, NaCl. It probably increases the flow of gastric juice, and generally it aids digestion.

3. An *acid* is a compound containing hydrogen and an electronegative element or radical, part or all of which hydrogen can be exchanged for a metal (or its equivalent) without the formation of a base. *Example,* sulphuric acid, $H_2SO_4$. A *base* is a ternary compound capable of entering into double decomposition with an acid to produce a salt and water. *Example,* sodium hydroxide, NaOH. A *salt* is a substance formed by the substitution of a metal (or its equivalent) for part or all of the replaceable hydrogen of an acid. *Example,* monosodic sulphate, $NaHSO_4$; and disodic sulphate, $Na_2SO_4$.

4. *Specific gravity* is the weight of a given volume of a substance as compared with the weight of an equal volume of some substance taken as a standard, under like conditions of temperature and pressure.

In *urinalysis* it gives a rough indication of the quantity of total solids. The normal specific gravity is about 1015 to 1025.

5. *Ozone* is an allotropic modification of oxygen; the oxygen is condensed and the ozone molecule contains three atoms of oxygen.

*Chemical affinity* is the force that binds atoms together to form molecules.

*Reagent* is something used to bring about a chemical reaction.

*Volatile* denotes a substance which evaporates at ordinary temperature.

*Ferment* is a substance which by its mere presence is capable of causing decomposition of organic substances under certain conditions.

6. *Test for albumin in the urine.* "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent, it is to be treated with a few drops of magnesia mixture and again filtered."

1. *The heat test:* "The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of $HNO_3$." (Witthaus' *Essentials of Chemistry.*)

*Test for pus.* The addition of caustic potash causes the production of a ropy gelatinous mass.

7. *Symptoms of acute arsenical poisoning.* "They usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities." (Witt-

*haus' Essentials of Chemistry.*) The antidote in acute arsenical poisoning is a freshly prepared solution of ferric hydroxide.

The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

*Treatment:* "The convulsions are to be arrested or mitigated by bringing the patient under the influence of chloral or chloroform as rapidly as possible; the stomach is to be washed out, and the patient is to be kept as quiet as possible." (Witthaus' *Essentials of Chemistry.*)

The *symptoms of poisoning by morphine* are as follows: "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours."

*Treatment:* "Wash out the stomach with a dilute solution of potassium permanganate, leaving about 500 c.c. in the stomach; and maintain the respiration. In the first or second stage the 'ambulatory treatment' should be adopted to prevent, if possible, the establishment of the third stage. If this stage develop the main reliance is to be placed in maintaining the respiration by artificial methods, until the poison has been eliminated. Strong coffee, or caffeine by the mouth or rectum, are of benefit. The same cannot be said of atropine. The urine should be drawn by the catheter."—(Witthaus' *Essentials of Chemistry.*)

8. *The most common constituents of urinary calculus* are: Uric acid, sodium urate, ammonium urate, calcium oxalate, calcium phosphate, and triple phosphate.

9. *Sugar in the urine may indicate:* Diabetes mellitus, lesion of the floor of the fourth ventricle, certain disorders of the liver, certain diseases of the brain or nervous system, or the presence of some poison in the body.

*Indican in excess* denotes: Putrefactive changes in the intestine or elsewhere, diminished peristalsis, deficiency of acidity of gastric juice, a gastric ulcer.

10. There are about eighty chemical elements.

*Five of the elements most commonly found in the human body* are: Carbon, hydrogen, oxygen, nitrogen, and chlorine.

ETIOLOGY AND PHYSICAL DIAGNOSIS.

1. Most cases of chronic endocarditis are the result of an acute endocarditis following chorea, rheumatism, or some infectious disease. It may also be caused by chronic nephritis, alcohol, syphilis, gout, excessive muscular exertion, or atheromatous or fibroid changes. *Mitral regurgitation* shows apex beat displaced downward and to the left, increased area of cardiac dullness, and a systolic murmur heard loudest at the apex, and transmitted toward the left axilla and the angle of the left scapula; the second cardiac sound is accentuated.

*Mitral stenosis* shows a presystolic thrill near the apex, area of cardiac dullness increased on the right side, and a presystolic murmur over the mitral area not transmitted; the second sound is accentuated.

*Aortic regurgitation* shows cardiac impulse forcible and displaced to left and downward, diastolic thrill may be felt over the heart, Corrigan's pulse can be recognized, the area of cardiac dullness is increased, a diastolic murmur may be heard over the aortic area and is transmitted downward; a presystolic (Flint's) murmur may also be heard at the apex.

2.

| LOBAR PNEUMONIA. | BRONCHIAL PNEUMONIA. |
|---|---|
| Generally a primary disease. | Generally, secondary (to bronchitis or an infectious disease). |
| Age has little influence. | Generally found in very young or very old. |
| Sudden onset. | Gradual onset. |
| Fever is high and regular. | Fever is not so high, and is irregular. |
| Ends by crisis between sixth and tenth day. | Ends by lysis, at no particular date. |
| Generally only one lung affected. | Generally both lungs affected. |
| The physical signs are distinct, and there is a large area of consolidation. | Physical signs indistinct, and the evidences of consolidation are indefinite. |
| Sputum is rusty. | Sputum is rather streaked with blood. |

3. *Appendicitis:* Acute pain in right iliac fossa, fever, localized tenderness, sometimes a tumor can be felt, rigidity of right rectus, nausea, and vomiting.

*Renal calculus:* Sudden agonizing pain, following course of the ureter and referred to testicle and penis, chill, cold sweat, collapse, rapid and feeble pulse, no fever, sometimes strangury.

*Gall-stones:* Sudden acute pain in right hypochondrium. Sometimes referred to right shoulder, chill, fever, rapid pulse, profuse perspiration, tenderness over liver, sometimes jaundice.

4. *Etiology of sarcoma and carcinoma* is unknown. Several theories have been brought forward, such as: Injuries, heredity, bacteria, protozoa, and "Cohnheim's theory of embryonic remains."

*Lupus* is a tuberculous affection of the skin.

*Lupus* is characterized by tuberculous nodules, slow superficial ulceration, and congested scar tissue.

*Carcinoma and sarcoma* are not thus characterized; and a microscopical examination is necessary to distinguish between the two latter. *Carcinoma* is derived from epiblastic or hypoblastic structures, possesses a fibrous stroma in which are blood vessels and lymphatics. *Sarcoma* is derived from mesoblastic structures, has no stroma and no lymphatics, and the blood vessels are in contact with the cells.

5.—

| CEREBRAL HEMORRHAGE. | ALCOHOLIC COMA. | OPIUM POISONING. |
|---|---|---|
| Deep coma; sudden onset. | Can be aroused by supraorbital pressure unless very profound. | Can be aroused unless very deep. |
| Pupils unequal or dilated. Contracted in hemorrhage into the pons. | Pupils normal or somewhat dilated. | Pupils contracted to pinpoint size. |
| Pulse full and slow, often arterioscle r o t i c h i g h - tension pulse. | Pulse more rapid than n o r m a l and full. | Pulse rapid, may be irregular. |
| Respiration slow and irregular. | Regular respiration. | Respiration very slow—may be 6 to 8 per minute. |
| Temp e r a t u r e higher on paralyzed side, but lower in rectum. | May be low or normal. | |
| Urine contains trace of albumin. | Normal. | Normal. |
| Hemiplegia with convulsions on one side. | | |

—(Eisendrath's *Surgical Diagnosis.*)

6. HIP-JOINT DISEASE. *Causes:* Tuberculosis. *Symptoms of first stage:* Night cries; lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain, swelling and deformity (either real or apparent).

*Symptoms of second stage:* Abduction, limping, pain, which is worse at night, apparent lengthening of the

limb, abscess, atrophy of thigh muscles, flexion of thigh, effusion into hip joint, and there may be crepitation in the joint.

*Symptoms of third stage:* Flexion, adduction, and shortening of the limb; the joint may be dislocated or ankylosed, or suppuration may occur.

7. *Typhoid fever* is caused by the bacillus typhosus.

*Acute gastritis* may be caused by irritation, improper food, poison, alcohol, too much food, infections.

*Typhoid fever* is of gradual onset, has splenic enlargement, characteristic rose spots, characteristic temperature chart, may give a positive Widal reaction and diazoreaction.

In *acute gastritis* all the above are absent; after taking food there is headache; dull pain in epigastric region, eructations, nausea, vomiting, furred tongue, and scanty high colored urine may be present.

8. In *extrauterine pregnancy*, there will be signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage. In *salpingitis*, the tubes are inflamed usually secondary to inflammation of uterus or to infection (either gonorrheal or puerperal), headache, pain in lower abdomen, history of menstrual irregularity, leucorrhea, tube is enlarged and tender.

9. *Chronic parenchymatous nephritis* generally follows an attack of acute nephritis, or else is due to prolonged exposure to cold and damp, phthisis, or malaria. The quantity of urine is rather less than usual, it is turbid, contains blood. albumin, and casts; urea is diminished; dropsy is present.

*Chronic interstitial nephritis* is generally due to alcohol, gout, lead poisoning. The urine is increased in quantity, is not turbid, may have a small amount of albumin, but this is inconstant; a few casts may be present; urea is diminished; usually no dropsy until cardiac failure occurs.

10. *Gastric ulcer* is due to hyperacidity of the gastric juice and lowered vitality or defective nutrition of the gastric mucous membrane; this latter may be due to injury or bacteria. It is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

*Gastric cancer* may be due to injury, or bacteria, but its etiology is not settled. It does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs sometimes after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; there is progressive emaciation; severe anemia and cachexia are also present.

*Gastralgia* is a neurosis, and may be associated with some nervous disease, or hyperacidity or hypersecretion of gastric juice. The pain is severe, is independent of eating, sometimes vomiting occurs, and frequently eating gives relief; restlessness and the nervous manifestations may be present.

(To be continued)

## Miscellany.

**London as a Health Resort.**—S. D. Clippingdale states that London life is to some people their *pabulum vitæ*—the material upon which they live. This has been markedly shown in the cases of certain men of great mental activity. "The air seems dead in this quiet country," says Meredith. "I must rush up to London to live." "Sir," said Dr. Johnson, when asked to accompany a friend for a walk in the fields, "when you have seen one green field, you have seen all green fields; I prefer looking on men and things—come, let's take a walk down Fleet Street." Johnson was born in Lichfield, and he was fond of visiting his native place; but he always said he felt more at home in London. To him the motley throng of the great metropolis was more congenial than the restricted circle of the small cathedral town. It may, perhaps, be fairly assumed that the output of his great brain would have been restricted had he lived anywhere but in London. Another lover of London and of Fleet Street was Charles Lamb, who writes: "I am naturally inclined to hypochondria, but in London it vanishes, as do other ills. The man must have a rare receipt for melancholy who can feel dull in Fleet Street." Fleet Street does not appear to be at the present day a very attractive street, but among literary men it has been known as the "blue matter of the world's cerebrum." No wonder, then, that men like Johnson and Lamb like it. The fondness for London is not the special attribute of great men, and Londonophilia has shown itself in an extraordinary way in silly people. A wit of the Georgian period had the roadway in front of his country house paved with cobble-stones, in order that he might hear the rattling of carts over them and so be reminded of London. Ford Maddox Hueffer has recorded the case of a Londoner dying at a distance who expressed his regret that he was not passing away in the Underground Railway; and Pett Ridge has told of the servant girl who, leaving London with her family, leaped from the carriage to kiss the last stone of the city.

But if London has its many ardent lovers, it also has its haters, and among the Londonophobists are those whose opinion is worthy of every respect. The depth of their antipathy to the place may, perhaps, be measured by the number of the epithets they use. Heine contents himself with two, calling London the city of "fog" and "porter"; Grant Allen uses five: "seething," "grimy," "opulent," "squalid" and "hungry"; and Ruskin employs six epithets: "foul," "rattling," "growling," "smoking," "ghastly."

But whatever may be its esthetic attributes, there can be little doubt as to its suitability for persons suffering from certain nervous dyscrasiæ; cases, not of true pathology, but of simple digression from normal physiology; cases of hypochondria, melancholia, insomnia, and neuralgia of nonorganic origin, the drug and alcoholic habits, and morbid introspection; cases, in fact, requiring the very opposite of a "rest cure." Sir David Ferrier has recently pleaded for what he styles "rational psychotherapy" in such cases; and by "rational psychotherapy" the author understood such means as are provided by the diversions of this great city. Its historic, artistic, and literary associations; its many picture galleries and museums; its numerous places of amusement; the business activity of the city; the Attic regions of Belgravia; and the Alsatian retreats of the East End all combine to produce a state of exhilaration not met with elsewhere. —*Proceedings of the Royal Society of Medicine.*

**Medical Bookkeeping.**—Sir John Collie states that the physician's accounts for the half-year or the year should be summarized in the shape of a profit and loss account and a balance sheet. In this concise form important points are grasped with a clearness impossible in any other way. Many men are apt to think of bookkeeping as an unimportant matter, but upon it may depend one's financial stability, peace of mind, capacity for continuing work, future independence, and provision for dependants in the event of death.—*British Medical Journal.*

### THE PHENOMENON OF PATHOLOGICAL ANTAGONISM; ITS RELATION TO DIABETES MELLITUS.

By HENRY S. STARK, A.M., M.D.,

NEW YORK.

The idea intended to be conveyed by the term "pathological antagonism" is the tendency of a morbid process to come to a standstill or to disappear on the supervention of another. This theory, it should be noted, does not comprehend the intrinsic tendency of individual pathological processes to become self-limiting in duration and extent, or to exhibit a tendency to spontaneous recovery, both as to structure and function. This latter phenomenon is one of the elementary episodes in human pathology, but is irrelevant to the matter under consideration. In the same way the converse of our proposition, namely the tendency of one disease to activate another of a different type, is also irrelevant.

The conception of a spontaneous antagonism between concurrent morbid processes to such a degree, that one may arrest or eradicate the other, although one of the present-day mysteries of disease, may be accepted as reasonably certain and not of rare occurrence. Whilst clinically this phenomenon, namely the spontaneous involution of a pathological process, is no stranger to most of us, a consideration of its origin would open up an interesting field of speculation. Admitting its existence, should we ascribe the phenomenon to some physical law, or to biological influences, or to chemical processes, or must we accentuate our ignorance in the assumption that the phenomenon depends upon an unrecognized pathological factor? But, whatever the explanation, we cannot get away from the fact that as an experience in practice it may become a potent factor in deciding the issues of a disease. In order to make clear what I mean by "pathological antagonism" let me recite some clinical examples, all of which are authoritatively established.

It is a well-known fact that an attack of erysipelas has been followed by the disappearance of neoplasms, even of a malignant type, also of tuberculous ulcers of the skin, of chronic eczemas, or lupus nodules, of syphilitic lesions, of keloids due to burns, of sarcomatous glands, of carcinoma of the mamma, and of the salivary glands. In some instances, the disappearance of the primary lesion was permanent, while in others it was temporary; in still others where a neoplasm was involved, the improvement was in the nature of a reduction in its size either permanently or otherwise. This exceptional behavior of erysipelatous attacks has been known many years. About twenty-eight years ago Busch[1] and Fehleisen of Germany availed themselves of this anomalous curative influence of erysipelas by making it the basis of a treatment for the cure of inoperable growths and of other lesions which resisted all methods of treatment. These observers were enabled to report a number of cures due to an attack of therapeutic or artificial erysipelas.

In our own country Coley[2] was the first to avail himself of this principle of treating inoperable neoplasms, by the employment of the Fehleisen organism, then later by employing the toxin only, and still later a mixture of the toxin and the *Bacillus prodigiosus*. As a result of a varied experience in this method, Coley concluded that the mixed toxins exercised "an antagonistic and specific influence upon malignant tumors." Here we have an illustration of pathological antagonism and a practical use of the phenomenon for therapeutic purposes.

Still other authenticated instances of the antagonism between pathological processes are the following: the cessation of pertussis upon the advent of measles, also the apparent cures of chronic suppurative processes, as of the ear, when complicated by one of the exanthemata. Gerhardt[3] cites some singular cases to illustrate the favorable influence of infectious disease upon concurrent chronic affections. In one case the intense pain of a trigeminal neuralgia stopped during the course of an acute pneumonia, in another case, a pneumonia seemed to abolish the pain of a bilateral sciatica from a sacral tumor. In still a third case, one of tuberculous ascites accompanied by a pneumonia, diuresis became so marked that for a time the ascites disappeared. Citations of this kind justify the belief that we are dealing here with something more than coincidence.

Typhoid fever is also a disease which appears to exercise decided antagonistic influences upon other diseases. It has been credited with causing the disappearance of a concurrent carcinoma of the breast, of a chronic glycosuria, of pulmonary tuberculosis, and of chorea. It has long been known to clinicians that after convalescence from typhoid fever, oftimes the former patient has become physically stronger than before the attack and also that he has remained long free from all disease. Is it not reasonable to suppose that this circumstance was the result of an action between antagonistic pathological processes whereby the system, so to speak, shed itself of pathogenic matter *in extenso*, leaving the host almost impregnable to immediate bacterial invasion.

In seeking an explanation of the nature and origin of pathological antagonism, it becomes apparent that our efforts are limited mainly to conjecture. Nevertheless, there are some fundamental biological principles which might be considered to exercise causative influence. The following are the more conspicuous: (1) Cellular activity. (2) The phagocytic power of leucocytes. (3) The hemolytic or bactericidal power of blood and the produc-

microorganisms, one species of bacteria will eventually prevail at the expense of the others. Clinically this is exactly what does take place when two inflammatory diseases attack an individual simultaneously, one or other of the two will usually gain ascendancy, the tendency to neutralization of one or other bacterial poisons soon becoming apparent. How important a rôle is played in the production of pathological antagonism by the bactericidal power of blood, is much a matter of future research. But I think we are justified in believing that human blood serum is endowed with this function to no small degree by reason of the bactericidal substances contained therein. These bactericidal or protective substances have been studied with reference to special diseases. Very recently Dochez,* experimenting with the blood of pneumonic patients, concludes that "these protective substances may play a part in the mechanism of recovery." Reasoning analogously it may be assumed that if human serum has pneumococcidal virtues it possesses corresponding power against other bacteria, and it may be further assumed that this bactericidal power is a relative one for different bacteria found in the same host.

The influence of different species of bacteria upon each other is of material interest. Clinical evidence is not wanting to show that two species may antagonize each other completely, or conversely, they may mutually develop each other. The incidence of a bacterial antagonism must be acknowledged. Thus we find that while the gonococcus is antagonized by the bacillus pyocaneus it is developed by the pus-generating cocci.

Antibody production as one of the body's defences against infection, no doubt, has some connection with antagonism of diseases. However, in the absence of definite knowledge whether immune reactions are all due to the same antibody or to a variety of them, we can make no definite statement concerning the association of antibodies to pathological antagonism.

Turning our attention to the ductless glands as a factor in disease neutralization we are confronted with some interesting revelations. To-day we acclaim the theory of the internal secretions and admit that the theory of autointoxication which held sway so long has not survived in favor. The theory of the internal secretions dominates the medical mind so universally that it has given birth to a new era in medicine. That it has unfolded a profusion of mysteries of the pathogenesis of disease, metabolic disorders especially, there can be no doubt.

Starling's discovery of a substance named by him "hormone," which stimulated intestinal secretion by chemical action, blazed a trail which developed a mass of biological data. Taking precedence over all is the reciprocal relation between the ductless glands.

This correlation may assume a twofold character, one in which two or more ductless glands antagonize each other through their internal secretions, the other in which the glands mutually reinforce each other in their effects, in the former instance functions are inhibited or disturbed, in the latter functions are stimulated to activity. Thus we find the interval secretion of the pancreas is antagonistic to that of the adrenals, shown by the fact that the pancreas inhibits while the adrenals excites the conversion of glycogen into sugar. The parathyroids antagonize the thyroid, shown by the appearance of glucose in the urine, after removal of the

parathyroids, whereas a glycosuria does not follow a thyroidectomy. The thyroid antagonizes the pancreas, shown after removal of the thyroid by the increased functioning of the pancreas, after removal of pancreas, fatal glycosuria, while after removal of both thyroid and pancreas, no glycosuria ensues. The hypophysis also is antagonistic to the pancreas, shown by the fact that in acromegaly glycosuria is very common. The internal secretion of the pancreas antagonizes the hormone, epinephrin, the latter has in consequence been employed therapeutically in severe diabetes. The internal secretion of the adrenals and hypophysis inhibit the secretion of the pancreas. As a consequence of the antagonistic influences resulting from a disturbance of the secretory balance we note a number of specific manifestations both of an anatomical and a physiological nature. Judging from the diversified phenomena following disturbances of these glands we are justified in concluding that they are capable of initiating favorable changes in one or other of concurrent diseases.

My particular interest in this subject arose from an observation of a number of unique and anomalous cases of diabetes mellitus in association with other disorders in which the glycosuria disappeared by reason of the complicating affection. I frankly confess the clinical and pathological evidence to establish such an antagonistic relationship is fragmentary at best; nevertheless, recent studies on the metabolism of diabetes has brought to light enough data to justify the general conclusion that such a phenomenon exists, potentially. If this phase of the disease has remained a mystery it is because diabetes itself, whether viewed as a disease or a symptom complex, has up to date baffled pathologist, bacteriologist and clinician. The cases to be considered can be arranged in three groups, as follows: (*a*) Those in which the glycosuria alternated with some other clinical symptom; (*b*) those in which the diabetes disappeared upon the establishment of some other disease; (*c*) cases in which a chronic glycosuria disappears permanently after a surgical operation. These three groups present such unusual features that it becomes impossible to apply the same theory of origin to all.

Group (*a*).—An example of this group is the following: A chronic glycosuria alternating twice in the same patient with urticaria, without any change of diet or medication.[5] Another example is a case of my own, in which a glycosuria alternated with the Wassermann reaction. I know of no other such case on record. It inaugurates a new field for research—the correlation of syphilis and diabetes. The patient in question, a male, came to me about sixteen years ago with a chancre which, together with the secondary and tertiary symptoms, ran the usual course. Treatment consisted in intramuscular injections of bichloride at first, then mercury by mouth and Zittman's decoction. About two years ago he developed diabetes, for which he was treated dietetically and with heroin. He never was given antisyphilitic treatment for the diabetic manifestations. Last Wassermann is negative: last glucose test postive. In this case the diabetes declared itself about thirteen years after the syphilis, and we could consistently argue that it was a syphilitic diabetes.

Another case of my own conjoining diabetes and syphilis is instructive. A confirmed diabetic female, under my observation about fifteen years for diabetes at a public clinic, contracted a chancre in the usual way, twelve years ago. The secondary and tertiary symptoms confirmed the diagnosis of the initial lesion. About a year after contracting the syphilis her urine became sugar free, while the usual manifestations of diabetes came to a standstill. In this condition she remained for several years, with never a sign of diabetes. Gradually diabetic signs again appeared and continued unabated to date. Last Wassermann, a few weeks ago, negative; last glucose test positive. Here we have a case, quite exceptional, in which the syphilis has no etiological relationship to the diabetes, and yet the latter seemed to stand in a constant pathological relationship to the syphilis. Salvarsan was not employed in either of these cases.

Group (*b*).—Namely, the disappearance of diabetes upon the establishment of another disease. As examples are to be cited the following, the cessation of diabetes after an acute pneumonia, typhoid fever, dysentery, scarlatina, and erysipelas.[6] It will be noted that this group comprises cases complicated by infectious diseases, which fact would lead us to suppose that the pancreas, in common with other organs, became secondarily involved from the primary infectious process. This group does not come properly within the scope of this paper.

Group (*c*) concerns chronic glycosurias which disappear after a surgical operation. Examples are the following: The apparent cure of diabetes after an appendectomy, or after drainage of the bile ducts. Such cases are classic. Also after extirpation of uterine and ovarian tumors even of a malignant type. The explanation of the mechanism involved in the cessation of the glycosuria in the third group is quite complex, but it appears to have an anatomical basis.

Carcinoma and diabetes seem to exercise reciprocal influences. I have found that if diabetes develop in a carcinomatous subject the intensity of the malignancy is in direct ratio to the severity of the diabetes; that is, a severe diabetes means a rapid progress of the carcinoma; a mild diabetes means a slow malignancy. If, however, a carcinoma develop in a diabetic the sequence is not the same, for at times the influence is favorable upon the diabetic symptoms, while at other times the latter are markedly aggravated.

The relation between diabetes and tuberculosis is worthy of comment. I have always believed that diabetics are no more susceptible to tuberculosis than they are to other diseases, and I think to-day authorities are a unit in declaring that the proportion of diabetics who run into tuberculosis is smaller than was given out a decade ago. Their susceptibility, as all know, depends upon a diminished resistance to bacterial invasion due to a hyperglycemia, or to a toxic substance in the circulation. It is, however, a strange fact that diabetes and tuberculosis are in a sense antagonistic, for experience has shown that whereas diabetics are prone to tuberculosis, the converse is likewise true, namely, that tuberculous patients rarely ever acquire diabetes. That this should be a mere coincidence is questionable. There must be a pathological foundation for a clinical event so exceptional.

While I am aware that I shall draw out much criticism in departing from old traditions concerning the pathogenesis of diseases, I, nevertheless, feel our views on the subject must be modernized to suit current concepts. I admit it is no easy matter to construct a theory of origin that can be

clothed with the distinction of accounting for the reciprocal influence of associated diseases, but if I have succeeded in arousing a sentiment in favor of the view that pathology is not yet a closed book I shall feel that my pen has been used for a good purpose.

## A CONTRIBUTION ON THE THYMUS.

By OTTO LERCH, A.M., M.D., Ph.D.,
NEW ORLEANS, LA.
Professor of Medical Diagnosis, Tulane University of Louisiana, Postgraduate Department.

The thymus is originally an epithelial structure which according to some observers is directly converted into lymphoid tissue, whereas others believe that mesodermal elements invade the epithelial organ. Still others believe that the medulla is derived from the endoderm and the cortex from the mesoderm. Some believe that the thymus is a blood-making organ basing their views by the mass of lymphocytes that pass from it; other observers hold that the organ attracts lymphocytes as nuclein carriers.

The thymus is in the first embryonal state a purely epithelial structure, vessels and interstitial tissue grow into it, and gradually a differentiation of medulla and cortex takes place. The organ continues to grow up to the second year, and during this period it is solid and full of secretion. Involution commences at the end of the second year and progresses up to the time of puberty. A small rest of parenchyma persists imbedded in Waldeyer's retrosternal thymic fat body, which preserves the form of the organ throughout life, and which, seen with the naked eye, can be recognized as something definite, something more than a mere fat cushion to support the large vessels.

Waldeyer published the results of his investigations in 1890. Hammar insists that it is incorrect to speak of a persistent thymus. Parenchymatous tissue remains until old age and the persistent thymus is normal, in comparison with other organs that atrophy with age. Notwithstanding the views of these prominent anatomists, it is still generally believed that the gland ceases to exist at the fifteenth or sixteenth year of life, and that fat and interstitial tissue with a few particles of parenchyma are all that remain at that time, gradually to disappear altogether. It is well settled that a close relation exists between the thymus, the thyroid, and the sexual organs. Castration causes continued growth and hypertrophy, and great sexual activity hastens the involution of the gland in animals. Involution of the thymus has an inhibiting effect upon these organs. The relation that exists between thyroid and thymus is shown in the case of the hyperplastic thymus when for various reasons the thyroid has atrophied or has become functionally insufficient.

Thymic hyperplasia is frequently found associated with goiter. Matt analyzed ten cases of exophthalmic goiter, in which the patient died shortly after operation on the thyroid, and found thymic hyperplasia in every one of these cases. He compiled 133 similar cases from the literature and found that in 76.5 per cent. of those that had died after operation the thymus was enlarged. Tetany following thymectomy is not as severe as that following ablation of the thyroid and parathyroids, and according to the observations of Bash not more than one-tenth of the dogs operated upon die in tetany. Thymectomy slows body growth and interferes with bony growth; the bones remain soft and fracture easy. According to Friedleben the thymus possesses a great vitality and can regenerate itself from a small residue.

Svehlo observed in 1896 that the intravenous injection of thymus extract in man and animals lowers blood pressure and increases pulse frequency. He showed further that the active principle formed after birth increases in strength with advancing years and remains active up to the fortieth year of life. His observations were confirmed by a number of investigators who found, however, that substances lowering blood pressure could be extracted from other organs and tissues and that therefore this action of thymus extract is not a specific one. It was further observed that the extract increases the coagulability of the blood and may cause thrombosis.

Paltauf described in 1889 a condition characterized by hypertrophy of the whole lymphatic apparatus, the glands of the neck, the axilla, the mesentery of the intestines, the tonsils, the spleen, and the thymus. Bartels added to this syndrome the presence of a small heart, narrowness of the aorta and peripheral vessels, a large brain, degeneration of the thyroid, a small vagina, and infantile uterus, with hyperplasia of the testicles and ovaries. This condition lowers the resisting power of the organism, and the patients die usually early, in consequence of the various acute infectious diseases—tuberculosis, nephritis, or diabetes—and suicides are frequent. The question whether the hypertrophied thymus is the cause or merely a symptom of this constitutional anomaly has not been solved.

Klose and Vogt sum up the state of knowledge about the thymus up to the year 1905. Extirpation of the gland does not influence the health of animals, nor retard their growth, nor cause trophic disturbances or rachitic processes, nor retard the healing of the fractures. The relatively large edematous brain was early noticed and the theory of thymic asthma due to pressure upon the trachea and large vessels had been advanced in 1830 by Kopp. This theory was later opposed and entirely denied upon the authority of Friedleben, till in 1888 Grawitz reestablished the former view. Rehn operated for a hyperplastic thymus in 1896, curing a case of laryngismus stridulus characterized by dyspnea and choking spells, and since that time a number of thymectomies have been performed with curative results, corroborating the old theory of pressure. Bash was the first to observe after thymectomy in animals a retarded growth, rachitic changes in the long bones, and changes in the psyche. Klose and Vogt who operated on fifty-four dogs with a perfected technique during the time of greatest development of the gland, namely

on the tenth day, divided the time after its extirpation into three stages: (1) the latent, lasting from two to four weeks; (2) the state of adipositas, lasting from two to three months; (3) the chachexia thymopriva and idiothia-thymopriva, lasting from

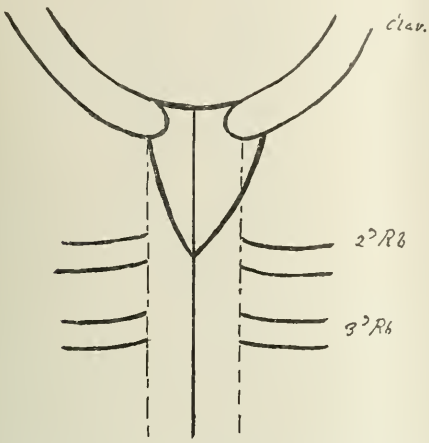

Fig. 1.—Thymic dullness. (After Friedjung-Kloze and Vogt.)

the third to the fourteenth month. Death occurs during thymic coma. They insist that the most favorable time of operation is between the tenth and twentieth day. After the third month only a small amount of glandular tissue can be found which persists to the second and third year. The following are conclusions drawn from their exhaustive investigations: Thymic death is a general chronic tissue death with a prominence of adynamia, especially of the bones and brain. Severe chronic disturbances may be expected after thymectomy in children at the end of the second year, which will probably end with death at the time of puberty. Thymectomy ought not to be performed during the time of greatest development of the gland. Metabolism is not influenced by this operation, nor can blood changes be found. The skeleton remains dwarfed and the bones become elastic and fracture easy. Rachitis, osteomalacia, and osteoporosis may be found in the same individual due to a decreased precipitation of lime salts, which is prevented by an increase of nucleinic acid in the system. The temperature is not influenced. Nervous disturbances are observed soon after operation. Motion remains awkward and slow, the animals tire easy and become paretic, coordination is disturbed, and the electric excitability of the nerves is decidedly changed, resembling the changes caused by tetany in children. Sensation remains long intact, but is gradually lost, and the senses, especially the sense of smell in dogs, become blunted. The skin reflexes are first increased, and later decreased, and the tendon reflexes already heightened in the latent state show a further increase later. In some cases a decrease may finally be observed. Psychic changes commence shortly after operation and progress till the animals pass into the idiotic state. Even in the latent state, the dogs lose their playfulness, and mental development is retarded. The perception of time and of space and the sensations of hunger and thirst are gradually lost, the dogs do not know their master, do not find the kennel dirty, eat wood and stone, and finally injure themselves. The brain is edematous and swollen, and microscopic examinations show degenerative and inflammatory changes in the nerves, cord, and brain.

The state of adipositas corresponding to the lymphatic diathesis in children is marked by a great accumulation of fat and by a hyperplasia of spleen, pancreas, thyroid, testicles, and ovaries. Children with a hyperplastic thymus have not alone to suffer from the pressure of the organ upon the trachea and vessels but also from the intoxication which gives rise to the lymphatic-chlorotic constitution (thymolymphatic state), a hyperplastic poorly functioning organ causes symptoms that resemble those due to its deficiency or absence. The loss of resisting power to infection and to psychic insults is the consequence. These children die often rapidly with the symptoms of shock.

The deficiency of lime salts in the bones after thymectomy, only half the normal, is due to an excess of acid. Their precipitation is caused by alkalies, their solution by acids. This suggests the hypothesis that the thymus through nucleinsynthesis, neutralizes phosphoric acid and its complicated compounds are set free in the growing portions of the organism, and explain the edematous condition of the central nervous system. Colloids swell in the presence of acid and water; they are found in every cell of the body and the cells of the brain are especially rich in these substances. An excess of acid causes edema. The edematous brain is a direct consequence of acid intoxication and acid neutralization through the function of the thymus is a life important process.

Thymus extract increases the symptoms of intoxication and alkalies given in sufficient quantity neutralizes the excess of acid and may stimulate alkali production. The feeding of the gland to normal animals increases their nervous excitability. The extract has been successfully used in the treatment of simple goiter; its administration does not cause hyperthyroidosis. Miculicz, who was the first to use it in this disease, also reported cases of exophthalmic goiter treated with favorable results. His experiments have been only partly confirmed.

Probably good results are obtained when hyperplasia is associated with degeneration and a poor functional activity. A number of other affections have been treated with thymus extract. In infantile marasmus, when atrophy of the thymus is present, which is usually the case, the medication gives good results. In rachitis, it is said by some and denied by others, that the insufficient ossification of bone is benefited. The function of the thymus is of importance to stimulate the growth in childhood.

Fig. 2.—Wilhelmina K.; tissue of mediastinum anticum resected and prepared.

In the present state of our knowledge of the thymus, it is important to diagnose its disease.

Surgery may be lifesaving when the organ is hyperplastic—in the thymolymphatic state. The stridor and the asthma are of great importance in the diagnosis of thymic hyperplasia and wasting in thymic atrophy. The examination with the Roentgen

Fig. 3.—Infant of 2 months; intestinal catarrh and inanition.

rays aids in some cases though it is unsatisfactory in most. According to Bash and Rohm it is impossible to make out with the *x*-rays the thymus in children, but hyperplasia of the organ can be diagnosed with this means according to Crotti, myself, and others.

Percussion gives good results and thymic dullness can be made out with accuracy in children. Park states in his article on this subject, published in 1912, that the area of dullness mapped out by Sahli and modified by Blumenreich holds to-day. I have confirmed this with Oestreich in a number of experiments on the cadaver, and have added that not alone the absolute dullness, but also the relative dullness, that is, the whole form of the gland, can be mapped out in children and in *adults* up to old age, when my method of percussion (drop method) is used.*

The gland is located in the anterior mediastinum, between the mediastinal leaves from which the internal artery and vein pass into it. It consists of a medullary and cortical portion and is surrounded by a fibrous capsule. A fine network of interstitial tissue, springing from the main capsule, divides the organ into a number of lobes and these into smaller lobes, and these again into follicles composed of adenoid and lymphoid tissue. Scattered in this are the concentric corpuscles of Hassal, which consist of a nucleated center, surrounded by flattened epithelial cells. The capsule is loosely fixed to the sternum and well grown to the fascia of the large vessels. The phrenic nerves and the pericardial phrenic artery border the thymus on both sides, which rests with its lower pole upon the pericardium, reaching usually to the fifth costal cartilage. The posterior surface lies upon the right auricle, accompanies the pericardium, ascending aorta, and aortic arch, and passes over to the pulmonary veins and reaches occasionally to the bifurcation of the trachea following the descending left innominate vein. It is in contact on the right with

the vena cava superior and right innominate vein, and rests above the left innominate vein directly upon the trachea, surrounded by the innominate artery, the left carotid artery, and the jugular vein. The pneumogastric and recurrent laryngeal border

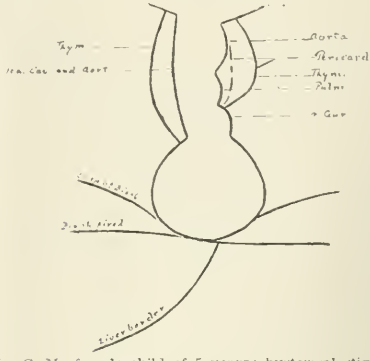

Fig. 5.—C. M., female child of 5 years; hysterical stigmata, movable heart, and enteroptosis.

it on the left. Branches of the internal mammary, inferior thyroid, the pericardial phrenic artery, the innominate and the superior thyroid supply the gland with blood, while only a single network of veins empties into the internal mammary vein. This decided disproportion between the afferent and the efferent vessels is of special interest, considering that the organ is in direct connection with the aorta and that it shares in every disturbance of the general circulation. Attention has been called to this feature by Klose and Vogt and previously by myself. The lymphatics are large, arise in the substance of the gland, and are believed to terminate in the jugular vein.

The theory of thymic asthma was founded upon the changing turgesence of the gland, its capacity to become hyperemic, to press upon the trachea and hinder the return flow of blood to the heart by its pressure upon the large veins. Hyperemia has been mistaken for hyperplasia. The most severe congestion disappears after death and leaves no trace at autopsy. Stridor and death have been

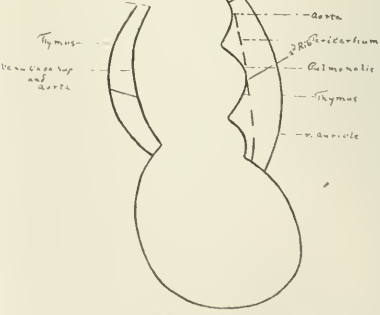

Fig. 6.—Mr. G., 48 years old; general tuberculosis.

caused by an acute increase in size, due to hyperemia, the gland pressing upon the trachea, the vessels, and the nerves. The sternovertebral diameter is not more than one-half centimeter in children, and though getting larger after the second year

the space allotted to the thymus remains small and the walls are unyielding.

Blumenreich mentions in his extensive work "Über Thymusdaempfing" (thymic dullness) that very little is found in the literature on the percus-

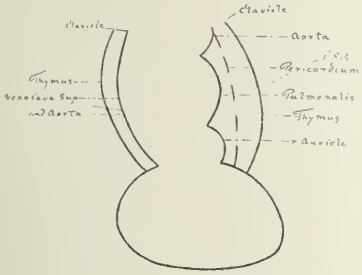

Fig. 7.—Woman with interstitial nephritis.

sion of the thymus. It was difficult to differentiate between a tumor in the anterior mediastinum an aneurysm of the aorta, enlarged bronchial glands, and a hyperplastic thymus, when a dullness over the manubrium sterni passing its borders reaching downward to the second and third rib, was found in children. He made his investigations on 100 living and dead children and outlines an area of thymus dullness, corresponding to the absolute dullness of the gland. He did not determine the real form and size of the thymus, which, largely covered by lung tissue, can give only a relative dullness. He percussed the borders of the lungs. The real form of the thymus made out by its relative dullness differs from the absolute, somewhat like the relative from the absolute heart dullness. However, he has proven that like the absolute heart dullness absolute thymus dullness possesses a distinct and characteristic form, which gives the exact position of the gland, and that changes of this are due to certain diseases. Situated behind the sternum upon the pericardium it covers the large vessels, reaches above nearly to the thyroid, and fills the space of the anterior mediastinum not covered by lung tissue, pushing the borders of the lungs apart. Considering only that portion of the thymus which is in direct contact with the anterior chest wall he finds its greatest width in line with the

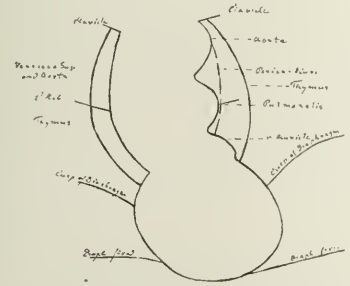

Fig. 8.—Small woman, 26 years old; general tuberculosis.

sternoclavicular joints and thence downward parallel to the anterior borders of the lungs converging in an oblique angle with a slightly rounded point. The dullness is small, between the second and third rib, and ceases between the third and fourth rib. The left half is usually larger than the right. He finds but little dullness and sometimes none at all in children that suffer from cholera or emphysema, and proves that absolute thymus dullness is represented by a triangle, the base of which

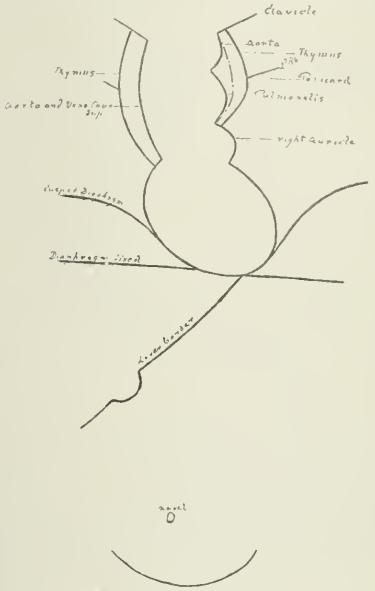

Fig. 9.—M. Cr., 39 years old; gastric ulcer

is situated in line with the sternoclavicular joints with its point usually below the second rib. Sahli who made his observations only on living children finds the lateral borders of thymus dullness almost vertical, a short distance outward from the borders of the sternum, passing downward into the heart dullness. Blumenreich concludes from his numerous observations that only a very slight difference

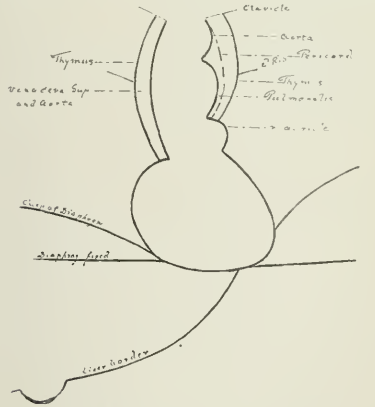

Fig. 10.—Mr. V., 38 years old; bronchitis

ante- and post-mortem exists and that this is caused by the borders of the lungs, which separate widely in expiration. The results of percussion in the living correspond closely to those obtained on the cadaver. He was able to percuss the thymus dull-

ness with certainty in children up to the fifth year, with the exception of patients suffering from cholera and emphysema. This is of special interest; in cholera patients it is probably due to the insufficient quantity of blood and lymph in the gland, in

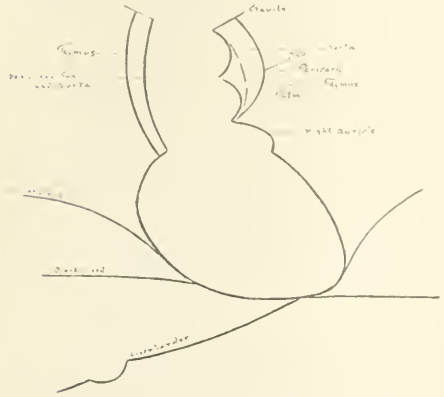

FIG. 11.—Mr. C., 58 years old; interstitial nephritis.

emphysema, to the distention of the lungs. After this time thymus dullness decreases in frequency, according to this observer.

For many years I have often found a dullness over the upper portion of the sternum and to its sides, which it was difficult to explain, and like others, I have taken it for aneurysm of the aorta, enlarged bronchial glands, or tumor.* Five years ago I was able for the first time to percuss the exact borders of this dullness in a neurasthenic, a brother of a patient suffering from exophthalmic goiter, and diagnosed it as intracostal thyroid, on account of its resemblance to a substernal struma. However, finding this dullness constantly in hysterics and neurasthenics, the only patients which at that time I examined for this purpose, and soon being able to determine with accuracy the large vessels, I had to come to the conclusion that it corresponded to and represented the old thymic tissue, excessively filled with blood. I was forced to this conclusion by the form of the dullness, which exactly corresponds to the form of the thymus and further, because it clears up considerably in the horizontal position of the patient, whether or not he lies on his stomach or on his back, and increases in the upright position. In many patients it is visible, full, protruding, and frequently red. Occasionally distended veins may be seen in it, which empty when the patient resumes the horizontal posture, the ribs are flattened and the intracostal spaces sink. Almost in every case it is marked like an organ on the chest wall, and can often be mapped out with the dermograph before percussion is made. I found enlarged thymus dullness so frequently associated with hysteria and neurasthenia and enteroptosis that I described this symptom complex as a distinct disease (MEDICAL RECORD, March, 1909). My assistant, Dr. Fossier, read a paper on the subject to the society.†

Grawitz, who was interested and who reviewed my paper in the *Berliner klin. Wochenschrift*, thought the condition would explain cases of exophthalmic goiter *sine* goiter. Kreuzfus, of the University of Vienna, thought I had mistaken intrathoracic goiter for the thymus. He sent me some of his skiagrams that resemble my charts.

The position and form of the dullness are always the same, in the male and in the female, in the infant and the aged. The upper border corresponds to that determined by Blumenreich, a line drawn through the sternoclavicular joints, and the lower border passes into the heart dullness. I can confirm Sahli's observations on living children, in so far as the outer borders of thymic dullness are found beyond the borders of the sternum, they are not, however, represented by vertical lines, but by circular segments, which lie beyond the sternal borders. Usually the left is situated further outward than the right, though the reverse may be seen as well. The figure is oval in shape and cut off above and below. Jointly with Prof. Oestreich of the University of Berlin we have shown on the cadaver (Fig. 6 and the case belonging to it) that the filling of the degenerated thymus tissue causes the dullness.

The old thymus filled with blood and lymph as well as the fully functioning organ in young children, is certainly of great importance during life, with respect to the cerebral circulation, considering the disproportion between the large blood supply to the gland and the paucity of veins emptying into the internal mammary, a comparatively small vessel. It was formerly thought that the thyroid serves as a reservoir to regulate the blood supply to the brain; it is the thymus probably that pos-

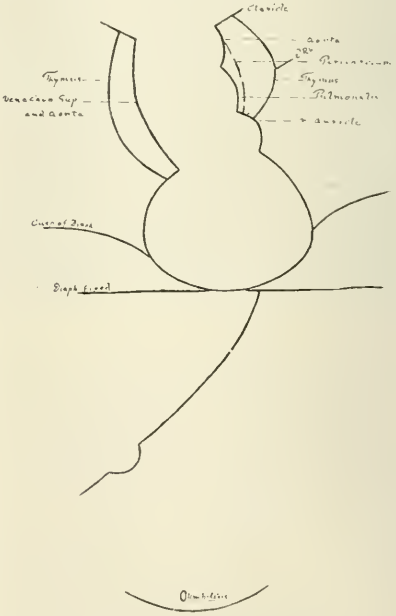

FIG. 12.—R., 25 years old; bronchial asthma.

sesses this function. Grawitz, with whom I discussed this question, agreed with me that the blood cannot escape freely. The dullness disappears after death in the adult and in a few hours nothing but pericardium and large vessels can be per-

*Thymus enlargement associated with nervous symptoms, MEDICAL RECORD, March, 1909.

†*New Orleans Med. & Surg. Jour.*, IX, 300, 302, 1909.

cussed, as only this, the lungs, the large vessels, the fat, and the interstitial tissue, the relic of the thymus, are located in the anterior mediastinum. It is evident that the old thymus causes the dullness, corresponding in form, size, and position

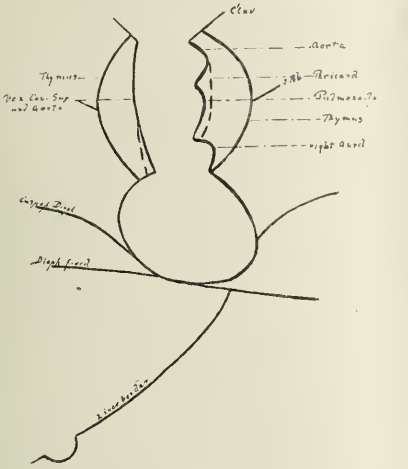

Fig. 13.—Miss A. M.; enteroptosis and migraine.

to this gland. The large filling of the organ with blood and lymph, changing readily with the change of position and attached to the large vessels, sharing in every disturbance of the general circulation, has, as far as I know, been considered by nobody before me.

The following cases may serve to illustrate the above conditions:

Fig. 1.—Thymic dullness after Blumenreich.

Fig. 2 represents the tissue of the anterior mediastinum (the thymic fat body) of a cadaver of a woman, 48 years of age, resected and prepared. It has the form of the dullness, smaller in the transverse diameter, and consists of fat, some interstitial tissue, and a few veins. Glandular tissue could not be detected microscopically.

Fig. 3.—Infant, 2 months old, who died of inanition and intestinal catarrh. Shows form, position, and size of thymus.

Fig. 4.—Thymus, vessels, and heart of an infant 8 months old, who died of a severe bronchitis and intestinal catarrh.

Fig. 5.—The same in a living neurotic child, 5 years old. Large thymus. The child is an enteroptotic.

Fig. 6.—Autopsy of a man, G. General tuberculosis, fatty degeneration of the heart. Pleura and lungs affected with advanced tuberculosis. Spleen, liver, kidneys, and peritoneum, tuberculous. Heart vessels and pericardium were mapped out by percussion, and, as usual, no dullness found beyond their borders in adults, after death. An injection of three liters of a formalin solution was then made into the femoral artery, and again percussed. A dullness of the exact form and position of the thymus, corresponding to the dullness made out in every living adult could now be determined.

This experiment proves that the dullness found in the living depends on the filling of the thymic fat body with blood and lymph.

Fig. 7.—Interstitial chronic nephritis. Pericardium contains large quantity of a serous liquid. Heart strongly hypertrophied. The right ventricle dilated; the left not. Congestion of lungs, liver, and spleen. Typical granular kidneys congested.

This case is of interest because the borders of the pericardium are pressed outward and secondly because the hypertrophy does apparently not correspond to the dullness. The heart was measured and it was found that the long and short diameters of the organ exactly correspond with the dullness mapped out. The walls of the organ were thick and no dilatation of the left ventricle could be detected. Left auricle and ventricle differ from the usual appearance in such cases. Oestreich and de la Camp have called attention to these conditions in their book ("Anatomy and the Physical Methods of Examination"). One must consider the direction in which the hypertrophy of the left ventricle can be noticed, whether in the sternovertebral or in the long diameter. In the first cases diagnosis is not assisted by percussion, nor does the skiagram aid. After percussion of the vessels and pericardium, and after it was shown that the dullness did not extend beyond the borders, an injection was made and the region was again percussed. The dullness characteristic of the thymus could now be readily determined.

Fig. 8.—Mrs. H., 26 years of age, small and emaciated. General tuberculosis; all organs tuberculous; pericardium and vessels percussed. A formalin injection of 3 liters was made, as in the other cases, into the femoral artery. During the injection a considerable swelling of the thyroid was observed and percussion determined a large dullness in the region of the thymus. This case shows goiter with large thymus in a small woman. The cusps of the diaphragm indicate the conditions of the lungs. To the left of the sternum almost absolute dullness, and to the right dullness over the apex and over several places. The autopsy revealed contraction of the left lung and within a large cavity filled with pus, corresponding to the percussion. The right lung emphysematous, with tuberculous foci, as mapped out.

Fig. 9.—Mrs. C., 39 years of age; enteroptotic; suffers from ulcer of the stomach. In this case, the thymus has the usual form and does not appear to be enlarged. This case illustrates that enteroptosis is not always associated with a hyperemic and distended thymus.

Fig. 10.—Mr. V., 40 years of age, 5 feet, 6 inches, 250 pounds. Thymic dullness; vessels and heart are small; bronchitis. Obese patients have usually a small thymus, thin people a large gland. This goes to show that the thymus is active in regulating fat metabolism throughout life.

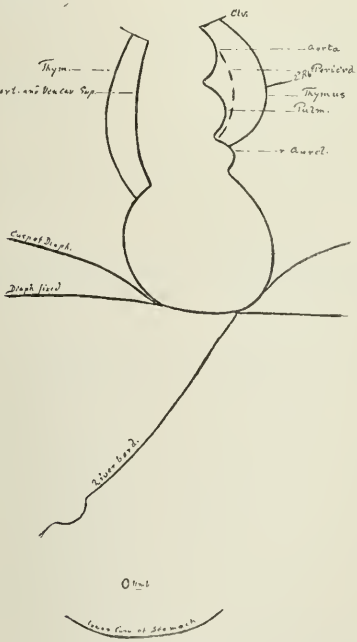

Fig. 14.—L., 19 years old; asthma and enteroptosis.

Fig. 11.—Mr. C., 58 years of age, 5 feet, 7 inches; interstitial nephritis; thymic dullness of the usual size; hypertrophy and dilatation of the left ventricle.

Fig. 12.—Mr. A. R., 25 years of age; tinsmith; enteroptotic; had not been able to work for more than two days in the week on account of severe and continued at-

tacks of asthma; had his first attack when 16 years of age, following hay fever, of which he was entirely cured, but has had asthma ever since. Thymic dullness, large and pronounced. Improved rapidly under treatment and can follow his trade without interruption.

Fig. 13.—Miss A. M.; enteroptotic; migraine and asthma on both sides of the family. Patient suffers from severe attacks of migraine, from three to four a month, each lasting several days; also suffers from choking spells. Improved under treatment and is now entirely cured; has been free from all attacks for over two years.

Fig. 14.—Mr. L., 19 years of age; has complained of asthma since childhood; attacks, two or three a week; enteroptotic and large thymic dullness. Improved under treatment, and can follow his occupation as clerk in a railroad office, without interruption.

Fig. 15.—Miss P., 37 years of age. Patient is 5 feet, 2 inches, weighs 350 pounds. Both sides of her family suffer from obesity. She claims never to have been sick in her life, but complains now of aching of the feet at night. When 12 years of age she weighed 160 pounds, at 25 200 pounds, and at present 350 pounds. Appetite, digestion, and sleep are good; bowels and menstruation regular; the blood is normal; blood pressure 175.

The urine is free of albumin, sugar, and casts, and

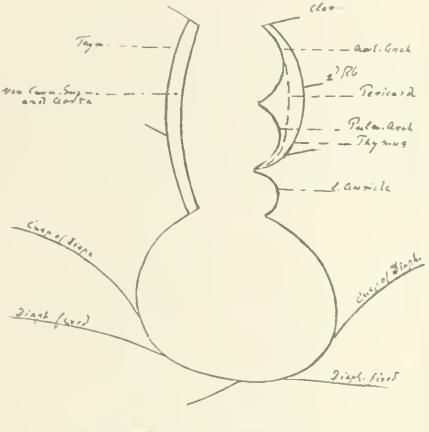

Fig. 15.—Miss P., 37 years old.

her organs normal. This patient, who has just come under observation, is of great interest, as she has a very small thymus dullness with an excessive adipositus.

Our investigations on the cadaver confirm the views of Waldeyer and Hamar, that the thymus persists during life, prove further that in a large number of cases it can be marked out upon the chest wall without percussion and in all with it; that it is well filled during life with blood and lymph, and that its turgescence changes on change of position, less in the horizontal and more in the upright posture of the person, and that it empties itself almost completely after death. Our investigations show further that the form and position of the organ remain the same throughout life. Comparing the form of the thymus when injected with formalin solution and its form during life, a difference can be detected. The side is more bulging on the left, reaches further down in the former than in the latter, though in every one of the asthmatic patients a resemblance is noticed proving that in these cases a great hyperemia exists and that the organ is stretched.

In analyzing these and similar cases characterized by the symptoms of the functional neuroses, hysteria, and neurasthenia; and the visceral neuroses marked by choking sensations, asthmatic attacks, fullness in the head and difficulty in swallowing, the hypothesis suggests itself that enteroptosis constantly associated with these conditions gives rise to this complex of symptoms. I have never examined a hysterical or neurasthenic patient in whom I did not find an enteroptosis, and Schofield reports 90 per cent. of his neurasthenic and hysterical patients to be enteroptotics. It is a condition especially suited to favor circulatory disturbances, frequently aggravated by a movable heart. The thymus shares in all of them, giving rise to pressure symptoms and to intoxication. Necessarily the cerebral circulation has to suffer and irritation of the centers, coupled with the congestion that exists in the abdominal organs and the anemia of the chest may well explain the various symptoms met with. The treatment bears out this view; that is, measures that influence the general circulation and restore its equilibrium benefit these patients most. The abdomen, usually pendulous, and the abdominal muscles relaxed, have to be restored to normal tone by suitable exercises, to insure an increase of intraabdominal pressure. Contracted abdominal muscles secure, with the up and down movements of the diaphragm, especially during deep respiration, a thorough massage of the abdominal contents, and restore tone to vessels and aid the heart. Deep breathing is therefore indicated with exercises to strengthen these muscles. Muscular tissue cannot be made at short order, and these patients need, therefore, a substitute to give relief. A well fitting bandage is the best for this purpose. The bandages usually displayed in the shops are useless; they are curved, do not exert pressure, cannot be fitted on the thin patients, and merely support the obese, that is, they fit them like a glove. I have designed a bandage that serves the purpose and have described it in the Medical Record, 1905, in an article entitled "Displacement of the Abdominal Organs." The bandage consists of a piece of elastic fitted in front above the pubes, held by leg straps, is buckled to a second shield across the spine. Three whalebones set straight give stability to the front shield. By means of the straps and the straight whalebones pressure can be exerted and regulated resembling that of the muscle, strongest above the pubes, less toward the navel, restoring the normal form of the abdomen.

Rest in the recumbent posture is another important measure in the treatment of these cases. Only in the most severe cases is continued rest of use. Intermittent rest, one to two hours after the noonday meal, and an early bedtime, are usually sufficient to help restore these patients to health. The blood has to be kept in the upper portion of the body by heart force and muscular tone. This is more difficult in these patients, and in our climate which, during the hot summer months, has a tendency to greatly relax the muscles. I have frequently seen the pulse reduced by 20 beats as soon as the patient lies down. Respiration slows in proportion; the blood flowing in a horizontal plane allows the veins to empty and the thymic dullness clears up, the arteries fill and the equilibrium is restored. (The importance of rest in the prevention and treatment of disease, *Therap. Gazette*, February, 1913.) The diet has to be regulated according to the climate and season, to the work the patient can still perform, whether he is fat or lean, young or old, affected with gastrointes-

tinal troubles or free from them. Fresh air is needed in these as in all other cases of sickness.

Organic diseases caused by the chronicity of the trouble or due to other causes has to be treated as in other cases. Thymus extract increases nervous symptoms. In 1909 I called attention to the usefulness of the treatment of an enlarged thymus with Roentgen rays and high frequency currents. It caused considerable contraction of the gland. Weil (*Bull. de la Soc., de Péd.*, 1912) uses *x*-rays to reduce the large thymus in children and Regaud and Cremien, who experimented on 40 young cats could cause complete involution of the thymus by this means. (*Lyon Méd.* C XVIII N 1) alkalies may be given to neutralize acidity and to stimulate alkali production. Surgery is indicated if medical treatment fails and may then be life-saving. I have mentioned previously the diseases in which the administration of thymic extract is of use.

1628 Upperline Street.

## THE CURE OF HABITUAL CONSTIPATION BY THE INTRAABDOMINAL USE OF OIL.*

By WATERS F. BURROWS, M.D.,

NEW YORK.

In a paper presented before the Surgical Section of the Seventeenth International Congress of Medicine entitled, "Postoperative Intestinal Stasis and the Intraabdominal Use of Oil,"† and elsewhere, the writer has advocated in abdominal surgery the use of comparatively large amounts of neutral mineral oil. Previously vaseline, vaseline oil, olive oil, animal oily extracts, and various fats had been used by others but in small amounts and with timidity, for which there is good reason on account of their impurities, and with results which have commended their use to few conservative surgeons. The principal object has been to control or prevent adhesions after such operations as are prone to cause them, whereas, when camphorated oil and other irritating substances have been resorted to, the purpose has been to set up a rapid chemical peritoneal reaction and congestion to combat peritonitis. The value, however, of neutral mineral oil, freed of impurities, has been overlooked.

To refer briefly to my original communication upon this subject, it will be noted that the use of neutral mineral oil is advocated in approximately 10 per cent. of cases of abdominal surgery, being poured into the belly at the conclusion of the operation in amounts of a few ounces to 10 or more, and to be used upon abdominal pads with greater frequency. Its advantages are: (1) It has no appreciable chemical action, no deleterious effect, and is slowly absorbed, at least in part. (2) It prevents, to a great extent, the formation or recurrence of adhesions. (3) It remains free in the abdominal cavity and does not form peritoneal accumulations. (4) It is most advantageously used upon pads or gauze, introduced within the abdominal cavity during operation, and, in the exceptional case, poured into the belly. It protects the abdominal contents from injury and eliminates or minimizes vomiting abdominal pain, and intestinal stasis after operation, and effects a safer, quicker recovery.

The predisposing causes of constipation are as numerous as the medicinal measures advocated for its cure. It is unnecessary to state that many such etiological factors are possible of elimination through nonsurgical means and various physical and medicinal forms of treatment render results. Nevertheless the number of cases of habitual constipation uncured and finally barely relieved by the usual treatment, the success of surgery directed toward the removal of mechanical abdominal abnormalities, and the general recognition of anatomical and physiological causes, has resulted, during the past few years, in a more general resort to surgical intervention. Perplexity has arisen, however, from the excessive number of procedures advocated by various surgeons, while the radical and complicated technique of many, and the considerable danger associated with some of the methods used has often deterred the physician from advising the necessary surgical relief.

Obstruction and interference with peristalsis in any part of the gastrointestinal tract and inflammation giving rise to harmful reflexes may result in constipation, and account for the costiveness which exists in cases of pyloric obstruction, functional or organic, gastric atony, gall-bladder and duct involvement, appendicitis, and similar conditions. Gastroenterostomy, cholecystectomy, and appendectomy performed for definite disease in these organs, result in cures, and the elimination of constipation, if present previously, in many instances. However, where the symptoms of disease are not typical and where evident associated colonic or rectal abnormalities exist such brilliant results are frequently not attained.

Constipation or more pronounced intestional stasis with putrefaction gives rise to irritating colonic reflexes and causes pylorospasm and abdominal pain, interference with gastric and intestinal peristalsis, and motility, and probably with gall-bladder evacuation. When the latter are secondary processes, the primary colonic condition, if left unrelieved, continues to cause symptoms after operation, more or less severe, and similar to those previously present. To determine the portion of the large bowel affected many hypotheses have been suggested by various observers, which, in brief, include ileocecal kink, appendical disease, cecal prolapse, mobility or atony, pericecal adhesions (Jackson's Veil), insufficiency of lieocecal valve, hepatic or splenic flexure obstruction, atonic colon, sigmoidal invagination or prolapse, general or local abdominal ptosis, intestinal adhesions, kinks or angulations, obstruction at the rectosigmoidal juncture, rectal and anal disease. Such may be the possibilities but the infrequency of some and the repeated occurrence of others is overlooked.

The operations resorted to, in the absence of uniform opinion upon the etiology, have been necessarily varied. The simplest have been for the correction of anorectal conditions, and the writer performs these under local anesthesia, almost exclusively, in his office, with results which prove that, in a certain percentage of instances, constipation originates here, and that, when the process is comparatively recent and not associated with secondary colonic or other abdominal complication, anorectal operations cure constipation. The operative relief of the intraabdominal condition may be free of danger or accompanied with considerable risk. With the various plastics upon the colon, division of adhesions, cecopexies, sigmoidopexies, operations for prolapse and similar relatively safe procedures the patient is seldom worse off after operation, and in

*Read before the Hudson County (New Jersey) Medical Society, January 6, 1914.

†"Postoperative Intestinal Stasis and the Intrabdominal Use of Oil," Medical Record, November 1, 1913.

suitable cases, a cure results, but the failure in many instances is attested by the increased frequency with which radical dangerous resections of a portion or entire colon, and intestinal anastomoses, especially ileosigmoidostomy, is resorted to. An authority states that a more or less simple operation like ileosigmoidostomy has been attended in his hands with a greater mortality than colonic resection, which indicates that the risks are not minor. While the mental attitude of some surgeons which leads them to carry out dangerous operations upon patients because the latter state they would rather die than continue thus to suffer, is generally unjustifiable. Constipation is not a fatal malady nor does it warrant the severe procedures that a cancer might require; it is relievable without surgical interference, and requires, when the latter is indicated, not a destructive but a conservative form of treatment. Considering the magnitude of an operation which removes the entire large intestine and the physiological and anatomical changes which necessarily follow, the wonder is that some remarkable results are attained but even with these in view it should be a method seldom chosen.

Habitual constipation, not due to abdominal inflammation nor to an anorectal affection, is usually associated with definite mechanical intraabdominal causes and a colonic radiographic plate will often show a cecal or sigmoidal abnormality, or general abdominal ptosis, although with these there may exist an inflammatory focus or colitis giving rise to a reflex spastic obstipation and causing irregular peristalsis and emptying of both intestine and stomach. Adhesions, angulations, and kinking may follow continued bowel stasis, or be formed following intraabdominal inflammation and act as exciting causes of constipation. Later the mesenteric attachments of the viscera become elongated, the upper abdomen is comparatively emptied while the lower is filled with prolapsed viscera, the belly wall is stretched, relaxed, and prominent, the intestinal musculature weakened and lacking tone, and at susceptible parts of the alimentary canal abnormal distention of the lumen of the bowel occurs.

To eliminate these causes of constipation adhesions need to be broken down or cut through, denuded peritoneal areas covered, angulations and kinks straightened, severe degrees of prolapse eradicated by gastro, ceco-, colo-, or sigmoidopexy, and a sufficient intraabdominal pressure created. After correction of apparent abnormalities, which in several instances has consisted solely in breaking down adhesions and eliminating kinks, the writer, in selected cases, pours 6 to 10 ounces of purified liquid petrolatum, preferably of high specific gravity, into the abdominal cavity. This oil prevents the recurrence of adhesions, lubricates the intestinal coils, straightens out angulations and kinks, floats the gas-filled loops of gut out of the pelvic cavity, exerts an intraabdominal pressure upon the viscera and is followed by a return of normal peristalsis and bowel evacuation. In the number of cases where his method has now been used the results have been uniformly satisfactory, in some a complete elimination of constipation is apparent and in the worst cases this simple safe procedure has given relief unattained by other means, and abdominal distress, gas accumulations, signs of toxic absorption, headaches, dizziness, insomnia, and the various symptoms of autointoxication, now generally recognized, overcome. Particularly following plastic nonseptic operations the later formation of bands and adhesions are prevented and thereby potent causes of postoperative intestinal obstruction and kinking, abdominal pain and chronic constipation, obviated.

The method commends itself as a prophylactic measure the oil to be used, in amounts of from 6 to 12 ounces, just before concluding many abdominal operations, especially in those cases where visceral trauma and irritation have been greater than usual and in which the liability to adhesion formation and kinking exists. Not infrequently constipation, absent prior, is present after abdominal procedures and may be attributed to these factors which, with the use of oil, are made noneffective.

That oil thus used is harmless has been shown by the writer through numerous animal investigations, and its effectiveness in the treatment of chronic constipation is proved. The object in the development of this new method has been to obviate the dangerous major operations which are constantly more often thought necessary and which the writer believes are followed by many failures, aggravation of the original trouble in certain instances, and a considerable mortality. Simple, safe, conservative, constructive measures are preferable, when feasible, and with the use of oil intraabdominally such a result, it seems, has been attained, constipation is cured, and radical extreme operative procedures are consequently rarely indicated.

40 East Sixty-second Street.

## PRACTICAL POINTS IN SURGERY.

By F. E. WALKER, M.D.,

Hot Springs, S. D.

Surgeon to Lourdes Hospital.

With a steady increase in cures, the result of surgery, there yet remains room for further advancement and improvement, not so much in operative technique, in sterilization of dressings, gowns, and instruments, cleanliness of the surgeon, his assistants, the operative field, etc., but more so in the preoperative and postoperative attention, preparation, and treatment of the surgical patient.

Many good surgeons of to-day regard the cleansing of the operative field while the patient is being anesthetized as amply sufficient. The emergency patients, of course, must receive treatment at once without regard for certain formalities, but the great majority of surgical patients are those who can wait a day or several days without trouble of any kind, and with these we should use every means at hand to guard against the probability or possibility of infection, as well as to endeavor by so doing to limit their stay at the hospital to the shortest time compatible with safety.

To do our surgical work correctly and with better results it is necessary that we go more into detail, take greater pains, and use more gentleness in handling patients than in the past. We must aim to eliminate every source of possible infection and minimize influences of a deleterious character, intrinsic and extrinsic, mentally, morally, and physically. There must be more care taken in preparation, in treatment, in technique, in giving of medicines and in diet. More abundance of fresh air in the hospital, more sunshine and more exercise are necessary.

It is a well-known fact that the intestinal canal is capable of giving up its numerous bacilli and produce mild, severe, or deadly infection, either from the normal bacilli which constantly inhabit

the colon from after three hours following birth up to the time of death of the individual, or from numerous transient bacilli constantly existing within the entire digestive apparatus and having a willingness to invade other structures upon the slightest provocation.

According to the researches of Gilbert and Dominic, we learn that the stomach normally holds 50,000 bacilli to the cubic millimeter. At the origin of the duodenum there are 30,000, with a gradual increase to the end of the intestine until 100,000 bacilli to the cubic millimeter are reached. The colon contains from 25,000 to 30,000 per cubic millimeter, and the entire canal contains a grand total of 411,000,000,000 germs. Of this number some 12,000,000,000 to 40,000,000,000 pass daily by way of the feces. These bacilli apparently do no harm in the healthy individual, but in the patient suffering from a disease which requires surgical intervention his vitality in many respects is lowered by reason of his disease, and the hardships incident to the operation and including the surgical trauma add to this lessened vitality to a greater or lesser degree.

Hospital locations are also a very important item. Our large city hospitals have been built where the surroundings could not be much more uncongenial. The undue heat in summer, the dust, dirt, smoke, and gas of the street which freely enters, the noise of rail and street cars and nearby elevated stations, the heavy wagons and other street traffic is constant, the roar and turmoil, haste and bustle and many other disturbing influences, and, above all this, the feeling, and justly too, of unfriendliness, are not conducive to the best interest of the patient. Neither do all these distracting elements superinduce a fellow feeling of confidence, either in hospital, surgeon or nurse. By the city bred who require hospital care perhaps no notice will be taken of these things, but the great majority of hospital patients come from the small towns, the villages, the farm, from homes of restfulness and repose, purer air, less noise, no confusion, and a knowledge of tried and true friendship. The large hospital is not the best place of refuge by any means, whether it be located in the city or smaller town. There are too much noise, too many hurrying feet, too much talk in the halls, too many bells in constant service, too little personal attention both by surgeon and by nurse, and too much dependence placed upon the unqualified and sometimes wholly incompetent interne.

Another feature of hospitals, both large and small, all over the country, is that of the hospital authorities allowing Dr. Tom, Dick, and Harry to enter the hospital and perform any or all surgical operations, regardless of his competency, his ability, or his record. His failures will necessarily be many, his cures few. His patients will need longer treatment, and his death rate will be correspondingly high. This lessens the good and brilliant results of the good men, cuts down the percentage of cures, and keeps the hospital standing at a commonplace level. He it is who puts the ban upon surgery, and his methods operate as a rank injustice to the surgeon, who is constantly endeavoring to do the highest class of surgery with the smallest percentage of deaths, and yet who may perceive in the hospital reports at the end of the year the mortality increased beyond what it should be. This percentage of increased mortality is due, not to the fellows in his class, but to those who are incompetent, who lack judgment and whose only real asset is their conceit.

I know of one large hospital which has not made a report of its surgical work for several years, because the men will not compromise their excellent work and splendid results with the class of men who do two, five, or ten operations a year with a high rate of mortality, or whose patients leave the hospital unimproved, when improvement should have occurred or who have simply improved when an absolute cure should have been the outcome.

There is ofttimes a reckless disregard in the handling of patients before, during, and immediately after operation, exposure to different temperatures without sufficient covering, all of which gives the already overtaxed system a new burden in the way of calling forth more energy to overcome a cooling of the body or in a subsequent battle with a cold of more or less severity.

Lastly, the matter of diet is no small item, for many patients are delayed in their convalescence by an injudicious diet, by improperly cooked and improperly served food, and frequently in quantities not at all commensurate with the patient's condition. The bowels, too, are often neglected, and may give rise to any one or more symptoms of serious disturbances because of the absorption of poisonous intestinal products, which leads to a lowering of the natural forces of resistance with a consequent failure of the wound to heal by first intention or with a disturbance of a more serious nature.

The organs of assimilation after operation, when food has been withheld for some days, are very active, and a certain portion of the residual intestinal contents is, therefore, much more easily absorbed. With early and free preoperative and postoperative elimination of an entire canal, no increased temperature or pulse rate should follow a clean case, as no blood is allowed to remain within the bowels, hence there is no occasion for the so-called absorption of fibrin ferment and a rise of temperature, and in the event some blood was left in the abdomen, in a properly prepared case absorption is so rapid and elimination so free that no irritation of the heat center occurs.

Pre-operative Measures.—In all of the "clean cases" the following rule should be observed: (1) After diagnosis has been made and the patient has entered the hospital a warm bath, followed by a blanket sweat (if patient is not too weak) should be given. The patient should be enjoined to take all the rest possible. The bowels should be moved the first day by calomel and salines. The rest of the time castor oil should be given night and morning. Large quantities of sterile water should be taken. The diet should consist of sterilized milk kumyss or milk punch the first day. This should be the diet up until noon the day before the operation, when nothing but sterile water should be allowed. Beginning with the first bath, the patient should receive a sterile toothbrush, and the teeth should be brushed three times daily and the mouth washed several times daily with some mild antiseptic solution. The nasal cavities should be sprayed with some mild antiseptic solution night and morning. The evening before the operation the operative field should be prepared and a large dose of castor oil given. The next morning the patient should receive an alcohol bath and a vigorous massage and the bowels should be flushed with a sterilized normal salt solution introduced through the colon tube. The field of operation is again gone over carefully with iodine.

During the time the patient has spent in the hos-

pital she has become acquainted with her surroundings, with her nurse and the surgeon, and has received an education which establishes her confidence to the fullest extent. Any impression made upon the average patient from system, care, and a constant endeavor to have every detail of preparation carried out, with a view of restoring her to health will certainly be of benefit.

Seventy-five minutes before the hour of operation a hypodermic of morphine ($\frac{1}{4}$ grain), hyoscin (1 100 grain), and cactin (1 64 grain) should be given. The curtains are drawn and a nurse is left in charge to soothe and quiet the patient, as well as to assist in the administration of the anesthetic. The enforced rest, diet, and free elimination, with all the emunctories working easily and harmoniously, renders the entire intestinal canal as nearly sterile as possible. The conclusions reached through the systematic studies of Marfan, Bernard, Cushing, and others are nicely summarized by Moynihan in his work, "Abdominal Operations": (1) The stomach contains, immediately after a meal, a number of microorganisms of different varieties, according to the nature of the food administered. (2) If the food is given in a liquid form it is rapidly passed onward into the intestines, and the bacterial forms are but slightly, if at all, affected. (3) If food is given in a solid form it remains longer in the stomach, and the number of bacteria contained therein undergo a steady diminution until digestion is complete. The empty stomach is then amicrobic. (4) The duodenum is often sterile; the number and virulence of the bacteria of the intestine increase in proportion to the distance from the duodenum, and attain their maximum at the ileocecal valve. (5) The *Bacillus coli communis* is the characteristic organism of the human intestine; it is never absent after the first few days of life. (6) The stomach and the upper part of the jejunum can be rendered sterile by administering only sterilized foods and by attention to the toilet of the mouth. In dogs, starvation for a few days leaves the upper part of the intestine empty and sterile. (7) The stomach and intestine, when their contents have been discharged and they are empty, are sterile. If the emptying is prevented by obstruction at the pylorus, or in the intestine, the contents dammed up behind the block contain organisms whose number and whose virulence are greatly increased.

Thus, if the canal can be rendered sterile by the administration of sterile ingesta, it goes without saying that an effort should be made to incorporate a rigid system of intestinal preparation in every available laparotomy.

Hospitals.—Hospitals should be small, and, if the number of rooms are eventually found to be inadequate, new buildings entirely separated should be erected and patients classified. Hospitals in our large cities should be far removed from the business center, and the influence mentioned elsewhere. A large lawn, nice trees, good scenery, flowers, homelike surroundings, and internal finishings provided, which will be as near like the average comfortable home as is possible and consistent with perfect cleanliness. It is a source of wonder to the country surgeon to learn of the number of recoveries obtained in the usual city hospital, where so many distressing conditions exist which are inimical to the best scientific interests of the patient. That a large majority of deaths result from these conditions must be admitted, and such deaths should not be attributed to the operation, but to the uncongenial surroundings and the lack of such things as contribute to the serenity of the mind. In the small hospitals, in the small towns, where the air is free from dirt, dust, smoke, and gases, where the peaceful quiet of old nature reigns, where tried and true friends are near, where life is quiet, peaceful, and full of hope, and where the simplicity of the average home is truly exemplified, where sham and glitter and display are unknown, where the surgeon looks after his cases, and is a constant and always a most welcome visitor, where nurses are known to be diligent and faithful and where sympathetic interest of all is apparent, there is a much lessened mortality than the great hospitals in the great cities can obtain, and it is gratifying to note the gradual though slow change that is taking place among the sick who need hospital treatment in favor of the small hospitals in the small places. Hundreds of such small hospitals are springing up all over the land and hundreds of the brainiest and most skillful men in the profession are filling the positions as surgeons in these hospitals and are daily performing the most difficult and delicate operations known to surgery, and with as good, if not better, results than hundreds of the so-called lights of the surgical profession, because the former have all nature to assist them and every influence to aid. These hospitals and these men have everything necessary to aid them in their work. The laboratories are well supplied with every needed scientific instrument of precision, both in the physiological, the pathological, diagnostic, and operative domains. The surgeon has access to the same teachings and he has more time for deliberate examination, the outlining of the treatment and the carrying out of technique than his city brother, who must needs pay for all the "superior advantages" in the big city, and therefore must hustle night and day that he may be able to keep up with the glittering lights of the fellows who lead the procession.

Handling of Patients.—In handling patients both before and after the operation great care should be used to keep them as warm and free from draughts of cold air as possible, and there is no excuse whatever for rough treatment, either in or out of the operating room. Solutions to be used in washing the field or inside of the abdomen should never be poured from a distance above 3 inches, and a thermometer should always be used to determine the degree of heat. The surgeon's or the nurse's feeling of the solution or having a little poured over the back of the hand to see if it is of the right temperature is so crude and unscientific as to warrant condemnation.

All internal organs should be handled with the utmost skill and delicacy, and retractors should not be used in the wound if at all possible to do without them. Hemostats should not be allowed to remain on the tissues for any length of time. All aseptic wounds should be sealed airtight with collodion by the double sealing method and no knots tied from the peritoneum up. The patient's room after the operation should be well darkened, the window raised to admit fresh air, and a nurse left in special charge for at least twenty-four hours, and pulse temperature and respiration recorded every two hours during this time. Hot water in minute sips does not satisfy the patient nor allay vomiting. It is far better to give as much cold sterile water as the patient wishes. Fewer patients will vomit; if they do vomit it is easier for them to do so, and the large quantity of water taken will

clean the stomach nicely in case of emesis, as well as make it easier for the patient, and in over 50 per cent. the large quantity of cold water will settle the stomach.

Diet.—The patient should be allowed only sterile water the first two or three days. The evening of the first day a large rectal enema of sterile soap and water should be given. The evening of the second day two grains of calomel divided into twenty doses, each dose ten minutes apart, is given, followed the next morning by two teaspoonsful of magnesium sulphate. As soon as the bowels have moved the patient is allowed sterile milk, kumyss, or broths every two hours for two days. Brandy, eggnog, and custards may be given. After this the light diet of soft boiled eggs, dried bread well toasted, and well cooked steak, thoroughly masticated and only the juice swallowed, should be given for two days, when the patient returns to a general diet. In this way it is possible for us to obtain better results than in any other method followed.

## LIVER ABSCESS.

By ADOLPH JACOBY, M.D.,

NEW YORK.

CLINICAL ASSISTANT GYNECOLOGIST, NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

In taking up the subject of liver abscess, I have a series of six cases to present, illustrative of the different etiological factors, and demonstrating the errors of diagnosis which are occasionally made.

Case I.—J. K., age 65. Family history negative. The patient is moderately alcoholic. He was admitted to the Beth Israel Hospital January 31, 1909. Thirteen days before admission he slipped on the ice and fell on the right side (lower costal region) against a smooth iron railing. He got up and walked off suffering only slight pain on the right side. There was no external evidence of trauma. Next day he vomited after taking food. This was repeated on several occasions. Three days later he began to cough accompanied by a sticking pain at the site of the injury. A few days later the cough became aggravated, and the pain shifted to the lower sternal and epigastric region, where it remained. He has had chills and fever several times. Bowels constipated. Urination slightly painful during the act. Has anorexia and is moderately prostrated.

Physical examination shows some cyanosis and dyspnea. The chest is barrel-shaped and has a limited expansion. The lungs show signs of chronic bronchitis and emphysema. The heart is normal. The abdomen is tympanitic; there is no dullness or flatness in the flanks. There is moderate rigidity and tenderness in the epigastrium and right hypochondrium. The liver is slightly enlarged and tender. Spleen is not palpable. Extremities are normal. A blood count on admission to the hospital was 17,000 leucocytes. The temperature was 102.2° F., pulse 104, respiration 32.

On February 1, temperature was 98°, pulse 100, respiration 36. The patient, feeling somewhat better, refused to stay longer in the hospital, and was sent out with the diagnosis of liver abscess. The diagnosis in this case was based upon: (1) The history of injury, falling on the right side. (2) Chills and fever. (3) Absence of signs in the lungs. (4) Absence of signs of fluid in the abdomen. (5) Rigidity and tenderness in right hypochondrium. (6) Enlarged and tender liver. (7) Leucocytosis of 17,000.

The case was not under observation long enough, and his subsequent course is unknown, so that it is impossible to arrive at a positive diagnosis. The nearest we can get is an opinion as to the probable diagnosis.

This case is illustrative of the occurrence of abscess of the liver by indirect violence, producing a slight abrasion of liver substance, forming a point of lowered resistance, which becoming infected forms a liver abscess.

Case II.—S. S., age 31. Painter. Family history, negative. Moderately alcoholic. This patient was admitted to the Beth Israel Hospital September 11, 1909. Six days before admission he suddenly had chills and fever. Next day he developed sticking pain in the right chest, aggravated by cough and respiration. He complained of general malaise, anorexia, and cough, which was moderately productive up to the time of admission. His chief symptoms then were the sudden onset with chills and fever, sticking pain in the right chest, aggravated by cough and respiration, and marked prostration. On physical examination he then showed a moderate amount of dyspnea and marked prostration. The tongue was dry and coated with a thick white fur. The glands were generally enlarged. In the right chest, anteriorly, beginning at the fourth interspace and going around laterally and posteriorly to the spine, three inches below the angle of the scapula, there was dullness, merging into flatness, extending down to the base of the lung. Breathing was diminished at this line, soon becoming absent near the base. There was an occasional râle heard over this area, The left lung was normal.

The abdomen was soft; there was slight tenderness and rigidity in the right hypochondrium; no masses were felt. The spleen was normal. The patient was otherwise normal. The urine examination made on seven separate occasions was always negative.

The blood count on admission was 22,800 leucocytes with a differential count of 86 per cent. polynuclear leucocytes and 14 per cent. mononuclear leoucocytes. On September 14 the count was 33,800 white cells, differential, 88 per cent. polynuclears, and 12 per cent. mononuclears.

An *x*-ray taken September 14 showed the diaphragm on the right side at the eighth rib; on the left side at the eleventh rib. There was no sign of consolidation. At this time the diagnosis was that of pleurisy complicated by pneumonia, and he was treated accordingly. On admission the temperature of the patient was 104° F., pulse 88, respiration 48. For the next five days the temperature was practically continuous between 103° and 104° F. On September 16 the patient had a hemorrhage from the bowels. Typhoid fever was suspected and the patient was put under typhoid treatment. Two Widal tests made on September 17 and 18 were both negative. A blood count on September 18 showed 44,200 white cells with a differential of 91 per cent. polynuclears and 9 per cent. mononuclears. The urine continued normal. For the next six days the temperature ran between 102° and 104° F., pulse between 90 and 106, respiration 28.

On September 22 the chest was aspirated and a brownish purulent fluid obtained which on examination was found to contain fibrin, degenerated cells, and a few polynuclear leucocytes. A blood culture taken on the same day was found to be negative. On September 23 another *x*-ray was taken which showed the arch of the diaphragm on the right side at the level of the fifth rib, throwing a sharp shadow, which indicates immobility of the diaphragm. On the next day the patient was operated upon. The operation consisted in a rib resection and drainage. About two and one-half inches of the eighth and ninth ribs were removed; the pleura was opened; no pus or fluid escaped. The pleura was then sewn to the upper surface of the diaphragm over the liver. The liver was then aspirated, and a serosanguinous fluid was obtained. The liver was incised at the point of aspiration, and a large amount of pus escaped. Two large abscesses were found at the upper surface of the liver. Rubber tube drains were introduced and gauze packing was inserted. The general condition of the patient after operation was very poor. The temperature for the next three weeks following operation was of the septic type, ranging from 98° to 103°, with daily rises. The pulse varied between 96 and 116, respiration 28 to 30. The temperature gradually came down, the range becoming less, and finally reaching normal and remaining so for the next seven weeks, with only an occasional rise to 101° or 102°.

The pulse varied between 80 and 100, respirations 20 to 24. A blood count taken October 9 was 12,200 white cells with a differential count of 82 per cent. polynuclears and 18 per cent. mononuclears. The wound gradually healed and the patient was discharged December 20 absolutely cured.

*Read before the Beth Israel Hospital Clinical Association.

This case is interesting because in the first place no positive etiological factor can be ascribed as the causative factor; and again it illustrates how readily the disease is mistaken for effusion in the right chest and pneumonia, especially if the onset is acute; and furthermore the value of exploratory puncture and *x*-ray in doubtful cases.

Case III.—N. M., age 47. Iceman. Family history, negative. Moderately alcoholic. At 17 the patient had an attack of pleurisy. Has had hemorrhoids since early adult life, which occasionally become inflamed. Never had any rectal inflammation. Five years ago he had an attack of abdominal cramps which were not localized.

Present History—The patient was admitted to the Beth Israel Hospital October 28, 1909. Two weeks before admission he developed diarrhea, having as many as five to eight movements a day. There was no blood in the stools. He had some tenesmus. He had no fever, headache, or bone pains. The patient became increasingly weak, and soon took to bed. He then developed some feverishness, headache, and general abdominal cramps. The fever kept ascending from day to day. He had several chills followed by fever, fall in temperature, and sweating usually accompanying the fall. The pain soon became localized to the right hypochondrium; was severe, continuous, aggravated by cough, inspiration, and pressure. The diarrhea ceased and was replaced by constipation. The chief points in the history were the onset with diarrhea, chills, fever, and sweats, and pain in the right hypochondrium. On physical examination the patient showed some dyspnea and slight prostration. The skin was hot and dry and showed a few suspicious roseolæ. The tongue was moist and covered with a thick white fur. The heart and lungs are normal. The abdomen showed marked tenderness and rigidity in the right hypocondrium. No masses were palpable. The liver was slightly enlarged. The temperature on admission was 102.6° F., pulse 92, respiration 24. For the next two days the temperature varied between 101° and 102°, pulse between 80 and 116. For the first few days the patient was treated as a suspected typhoid. The urine examinations on two occasions was negative. Three consecutive examinations of the blood gave the following results: 19,000 white cells, differential, 84 per cent. polynuclears, 16 per cent. mononuclears; 17,400 white cells-differential, 90 per cent. polynuclears, 10 per cent. mononuclears; 19,200 white cells-differential, 89 per cent. polynuclears, 11 per cent. mononuclears. These counts taken in conjunction with the tenderness and rigidity in the right hypochondrium, the enlarged painful liver, and the chills and fever, led to the diagnosis of suspected liver abscess. To verify the diagnosis the liver was aspirated. A mixture of blood and pus was obtained, which on examination was found to contain degenerated cellular elements, and which was negative as far as bacteria were concerned. The patient was operated on November 1, 1909.

The operation consisted of a rib resection and drainage. An incision was made over the tenth rib, and a portion of the rib was removed. The liver was aspirated; a slight amount of turbid fluid was obtained. The fluid appeared bloody and contained flocculi. An incision at the point of aspiration was made into liver tissue and a large amount of pus escaped. The liver cavity and the subphrenic space were packed with gauze. The condition of the patient after operation was fair. For the next four days after operation the temperature ran between 101° and 102.8° F., with a pulse rate of 80 to 110. In the four days following the temperature came down gradually, reaching normal and remaining so for the next sixteen days. The discharge gradually became less and disappeared. The wound closed and the patient was discharged cured with a temperature of 98°, pulse 80, and respiration 22.

Case IV.—H. G., 52 years old. Family history, negative. Two weeks ago the patient had an attack of gallstone colic, and was jaundiced for three weeks thereafter. She was admitted to the Beth Israel Hospital April 1, 1909. Two weeks before admission she began to complain of a sudden attack of pain in the right hypochondrium. The pain radiated downward toward the pubis. She had a marked chill that day followed by high fever. She has had chills and fever up to the day of admission. She has vomited frequently a greenish fluid. Her bowels have moved daily; the color of the stools were not noticed. The urine was high colored. During the past week the patient has become much weaker. Examination on admission revealed no jaundice; she was slightly cachectic. The heart and lungs were normal. The abdomen was soft and tympanitic except over the right hypochondrium, upper right lumbar and epigastric regions, where there is dullness, marked tenderness, and a large mass palpable. The free border of the liver was two inches below the costal margin; otherwise negative. The urine on four examinations was found negative. The blood count on admission was 10,400 white cells, with a differential count of 81 per cent. polynuclears and 19 per cent. mononuclears. The temperature on admission was 102.8° F., pulse 100, respiration 28. For the first four days the temperature varied between 100° and 102° F., pulse 96 to 118, respiration 28.

At this time the patient was thought to have gallstones with complicating suppurative cholecystitis. The temperature gradually assumed the septic type, and operation was decided upon. The operation performed April 4, consisted of a celiotomy and drainage for gangrenous gall bladder. The abdomen was opened through a high right rectus incision. The liver was found to be markedly congested and enlarged, reaching down to the umbilicus. On lifting up the edge of the liver a large amount of dark brownish purulent material was found exuding from its surface. The purulent material was traced to a cavity opening on the under surface of the liver and extending some distance into the liver substance. The cavity was situated near the transverse fissure. The gall bladder was found to be gangrenous and sloughing throughout its entire extent. Small pieces of gall bladder were removed with forceps. A large amount of the same purulent material came from the gall bladder. A stone, the size of a pigeon's egg, was removed from the cystic duct, through the gall bladder. About one and one-half inches to the left of the first abscess cavity another opening was found in the liver substance, from which a large amount of the same purulent material escaped. The under surface of the liver was well separated and walled off from the general abdominal cavity by strong fibrous adhesions reaching to the stomach and duodenum. The cavities in the liver were drained; the abdomen was closed. The general condition of the patient after operation was poor. For the next week following the operation, the temperature varied between 99° and 104° F., pulse between 96 and 120, respiration between 24 and 40. The temperature ran a typically septic course with frequent chills. During the third week the temperature varied between 98° and 102.8° F., pulse between 80 and 118. The patient gradually became weaker. At the time of death, April 23, the temperature was 102.2° F., pulse 116, respiration 24.

This case is interesting as an example of the origin of abscess of the liver by the extension of an infection of contiguous organs, which is quite a rare occurrence. No autopsy was permitted on the case, so that a more complete knowledge of the pathological conditions present was not possible to determine.

Case V.—Age 18. Operator. Family history, negative. Has had attack of nosebleed for the past three years. The patient was admitted to the Beth Israel Hospital January 27, 1910. Five days before admission he was seized with malaise, headache, chills, fever and cough. The chills were repeated daily, and almost always in the evening. The temperature was higher in the evening, and would remit or intermit in the day time. The fall in temperature was accompanied by profuse sweating. The cough was dry and unproductive, accompanied by sticking pain in the right chest. He had no hemoptysis. The dyspnea and prostration kept increasing. The bowels were markedly constipated. He vomited three to four times during the past five days. The chief symptoms were—the dyspnea, cough, sticking pain in the right chest, chills, fever and sweats, and prostration. On admission the patient showed moderate prostration and dyspnea. Normal resonance over the apex of the right lung anteriorly up to the fourth rib. Below this level there is dullness, diminishing breathing and crepitant râles. In the right axilla below the fifth rib, there is flatness, diminished tactile fremitus, diminished breathing, and crepitant râles. Posteriorly—From the

spine of the scapula downward, there is dullness merging into flatness, diminished tactile fremitus, and diminished breathing. The left upper lobe shows normal resonance. Anteriorly—Below the sixth rib in the axillary region, there is flatness, diminished breathing, and crepitant râles. Posteriorly, from the angle of the scapula downward there is dullness, and subcrepitant râles. Heart is normal.

The abdomen was distended and tympanitic; there was slight tenderness and rigidity in the right hypochondrium. No masses were palpable. The liver—The dulness merged with the pulmonic flatness, as above described. The dulness extends to three fingers below the costal margin. The free border was not made out owing to the rigidity. The temperature on admission was 103° F., pulse 120, respiration 32. The blood examination January 28, showed 12,000 white cells with a differential count of 88 per cent. polynuclears, and 12 per cent. mononuclears. On February 3 12,000 whites with a differential count of 85 per cent. polynuclears, and 15 per cent. monouclears. The urine on eight consecutive examinations was negative. On February 1 the patient's right chest was aspirated. Serous fluid was obtained: a smear showed 90 per cent. polynuclears. Since January 29 the breathing has become bronchial below the spine of the scapula on the right side, with a few subcrepitant râles at the end of inspiration. In the axilla, and below the fourth rib anteriorly on the right side, the breathing was very much diminished; occasional subcrepitant râles heard at the end of inspiration. The signs on the left side remained practically the same as on admission. In the axilla the rales disappeared, and there was flatness and diminished breathing over the stomach area.

February 3—The noteworthy points in this case to date have been: (1) Irregular remittent temperature. (2) Respirations averaging 28 per minute. (3) History of chills, fever and sweats. (4) Scanty expectoration, not rusty. (5) A leucocytosis of 12,000 with 85 per cent. polynuclears. (6) Increasing signs of effusion anteriorly in the right axilla, the flatness reaching to the third intercostal space anteriorly, and the fourth in the axilla, with markedly diminished or absent breathing and disappearance of rales over these areas, while posteriorly the rales have become more numerous, and the breathing bronchial, except over the extreme base where it is diminished. (7) Distinct bulging of the right chest, and obliteration of intercostal spaces. (8) Marked tenderness over the lower part of the chest anteriorly and in the axilla, and in the right hypochondrium. In view of these facts, liver abscess was considered. The patient was aspirated in the fifth interspace anterior axillary line; the needle was plunged in for about one and one-half inches. A thin red purulent fluid was obtained; which on microscopical examination showed broken up pus cells, and cells of polygonal shape with large nuclei and pigment granules. These were assumed to be liver cells. Streptococci and staphylococci were also found.

Another aspiration was made on the left side in the eighth interspace scapular line. No fluid was obtained.

February 4—At 3 A.M. the patient had a chill, and the temperature rose to 104° F., pulse 136. Signs of fluid were more marked this morning, posteriorly as well as anteriorly and in the axillary region. Bronchial breathing was no longer obtainable over the right lower lobe. It was then decided to operate. The operation consisted of a rib resection and drainage for liver abscess, subphrenic abscess, and empyema of the right side. Pus was located in the tenth interspace with an aspirating needle. An incision was made over the ninth rib in the midscapular line. About two and one-half inches of rib was removed. The pleura was exposed; the parietal pleura was opened, followed by the escape of a large amount of chocolate colored pus. The pleural cavity was explored, and a pus cavity was found leading downward through an opening in the diaphragm (the diaphragm being necrotic at this point). The liver tissue was palpated through this opening. A profuse discharge of pus came from the subphrenic space. Owing to the precarious state of the patient, further exploration of the liver was omitted. Two rubber drains and gauze packing were put into the wound. The general condition of the patient after operation was very poor.

For the six days previous to the operation, the temperature ranged between 100° and 103.6° F., with daily rises. The pulse varied between 90 and 120. The respiration 22 to 32. For the following four days after operation the temperature ranged between 98.6° and 101.4° F., with the pulse between 96 and 108. For the next nine days the temperature ran between 98.6° and 102°, pulse 92 to 120. In the following five days the temperature came down, reaching normal, and remaining there for the next six weeks; when discharge from the wound having ceased, and the wound being closed, the patient was discharged, March 30, 1910, with a temperature of 98° F., pulse 84, respiration 24.

This case is of interest because of its onset with symptoms pointing to a lung condition, and masking the underlying condition in the production of the symptoms. There is no evident etiological factor involved, and it would be hard to say just what was the cause of the production of the disease. As to whether the fluid in the chest was caused primarily by a perforation through the diaphragm, or whether the fluid was the result of aspiration, is questionable.

In all probability there was a real perforation of the diaphragm, as the signs of fluid were noticed to be more marked before the aspiration; and at the time of operation a portion of the diaphragm was found to be necrotic.

Case VI.—I. F. Age 46. Presser. Family history, negative. For the past twenty years the patient has been having attacks of pain in the abdomen. These pains were indefinite, lasting a few days and passing away without causing any very severe disturbance. During one attack, the patient vomited several times, a greenish material. There was no blood in the vomitus, or in the stools. He never had any jaundice.

He was admitted to the Beth Israel Hospital October 5, 1910. Six days before admission the patient had a severe attack of pain, mainly in the epigastric and right hypochondriac regions. With the pain he had attacks of fever, chills and sweating. He complained of severe headache. There was no vomiting or jaundice present. The bowels were constipated. The physical examination on admission showed some dyspnea. No cyanosis or jaundice. The heart and lungs were negative. The abdomen was distended. There was marked pain tenderness and rigidity in the epigastric and right hypochondriac regions. The liver was enlarged and tender. The examination revealed nothing else abnormal. The temperature on admission was 103.2° F., pulse 108, respiration 36. The urine examination was negative. The patient was operated on the same day.

The operation consisted of an exploratory laparotomy for a local peritonitis. A median incision was made about three and one-half inches long. The peritoneum was exposed and opened. The left lobe of the liver was found to be enlarged, firm and tense. A probe passed into the liver revealed no pus. The liver was then aspirated, and pus was obtained. An incision was made into the liver over the point of aspiration, and two large abscess cavities were found. These cavities were opened and explored. The cavities were found to contain pus and necrotic liver tissue. Two B.M. drains were introduced, and the abdomen closed. The general condition of the patient after operation was fair. An examination of the pus from the liver abscess failed to reveal any organisms. The urine on the day following the operation showed a trace of albumin and a few granular casts, probably as the result of the anesthetic. For the first three days after the operation, the temperature was 100° F. and the pulse between 80 and 92. In the next four days the temperature ran between 100° and 102°, the pulse 80 to 106. For the next sixteen days the temperature was of the septic type, ranging between 98.6° to 103° F., usually reaching its highest point about 6 P.M.; the pulse was from 90 to 124.

Since the operation the patient has continually complained of cramps and abdominal pain. From October 14 he has been having frequent bowel movements. On October 23 he had five bowel movements. On October 25 blood was noticed in the stools for the first time. Repeated examinations of the stools failed to show any amebæ. An examination of the pus likewise failed to show any amebæ. The patient was getting weaker every day. About nine hours before his death

the temperature became subnormal, 95.2 F., pulse 108. Just before death, the temperature was 96.8° F. An autopsy was permitted in this case. It showed the liver very much enlarged. Large abscesses were found in the right and left lobes communicating with each other. The colon, sigmoid, and rectum showed, on opening, numerous dysenteric ulcers.

This case is of interest as a case of undoubted dysenteric origin, as revealed by the autopsy findings, in which no amoeba were found at any stage of the disease.

*Summary.*—To sum up our series of cases, it will be found that, as regards etiology:

1. One case (case I) was due to mechanical injury, indirectly causing a contusion of the liver, and thus furnishing a point of lessened resistance to the action of bacteria.

2. One case (case IV) was due to the direct extension of the infection from a suppurating and gangrenous gall bladder; the abscess being formed on the under surface of the liver.

3. Two cases (cases III and VI) were due to dysentery. In one case (case VI) autopsy confirmed the presence of the etiological factor.

4. In two cases (cases II and V) no definite etiological factor could be assigned.

*Diagnosis*—In all our cases a constant finding was pain and tenderness in the right hypochondrium, and an enlarged liver. To this was added daily attacks of chills, fever and sweats. A leucocytosis was present in the majority of cases. In two-thirds of the cases there was a history of a definite etiological factor. The two cases in which no definite etiological factor could be assigned began with signs of pleurisy and pneumonia. One of these cases was subsequently thought to be typhoid fever (case II). Another of our series entered the hospital with a diagnosis of suspected typhoid fever. Another case in the series (case VI) entered with a diagnosis of perigastric ulcer. Among the conditions which liver abscesses are mistaken for are, malaria, right sided empyema, subphrenic abscess, echinoccocus cyst, and Charcot's hepatic fever. In doubtful cases the diagnosis may be made by exploratory puncture as was done in three of our cases (cases II, III and V). The *x*-ray is also helpful.

*Prognosis*—In our series of cases we had two deaths; a mortality of 33 per cent. The mortality of liver abscess is usually placed at from 20 to 30 per cent. One of our cases which recovered (case V) was complicated by perforation through the diaphragm, into the right pleural cavity, making 17 per cent. of ruptures, with 100 per cent of recovery. Rupture is usually placed at 28 per cent. of cases with 75 per cent recovery, if into the pleura or bronchus.

*Treatment*—As to treatment there is not much to be said. The treatment is operative, with free drainage above or below the diaphragm, depending upon the location of the abscess. In the amoebic forms it is not sufficient merely to operate for the abscess, the bowel must be treated at the same time in order to get results.

In *conclusion* let me say that very little is to be found in modern works upon the subject as compared to what is written on other diseases. For that reason, I hope that the presentation of this series of cases will serve to call your attention to this condition, and awaken in your minds the possibility of its existence, whenever confronted with signs pointing to the right hypochondriac region.

1141 Fox Street.

## THE INTERNIST AND SEMINAL VESICULITIS.*

By THOMAS A. KENEFICK, M.D.,

NEW YORK.

The knowledge of a reflex action is elemental. The dynamic energy, or so-called "tonus" vibrating from center to periphery, and the chemico-electric force of protoplasmic origin, reinforced by hormones, is now admitted. "Whatever energy is exerted when producing these phenomena is derived from the common stock of the universe." (Huxley.)

We have here a constant, dynamic force, controlling tubular and solid organs, governing speed, regulating blood supply, stimulating metabolic interchange and sustaining the chemical balance in all glandular secretions. This energy depends on its inherited or acquired quality, and absence of toxic or inflammatory irritants in the cell protoplasm, for these may pervert any particular function in the deep centers of the cord or cells of the cortex. No irritation at the periphery is so slight as not to create response at the center; no exhibition of motor activity but has its origin and strength in the cell protoplasm while all reflex change in vessel caliber depends on vasomotor influence.

"The vasomotor and trophic centers which control metabolism are peculiarly impressionable to peripheric irritation and hence through the intermediation of this nervous apparatus important changes may be wrought by even slight irritation." Toxins and inflammatory products change the anatomy of the peripheral nerve endings as in neuritis, and pervert the functions of deeper centers, exhibiting symptoms such as queer impulses, horrible dreams, depression, melancholia, and disturbed vasomotor stability.

We are awakening to the fact that man as well as woman may be a victim of the nervous symptoms from irritation or from pathological or toxic sources in his organs of generation. In the female this region has received very careful research, while its importance in man is just beginning to be recognized and studied scientifically. The seminal vesicles and their diseases grow in importance because of their intimate association with the mind. Symptoms pointing to mental or nervous disturbance, are often found to be due to local irritation, a pathological vesical change, or some simple unhygienic state of the sexual region.

"The seminal vesicles are fibrous tubes six inches long when extended, having a muscular and fibrous coat, an internal epithelial layer with its own secretion." (Gray.) The generative organs are governed by the sympathetic system, are autonomic, that is, capable of acting spontaneously and independently and of being excited mentally without voluntary irritation. "The glans penis is supplied by protopathic sensibility, with its delicate expansion for the three sets of extremely sensitive nerve filaments, quickly responding to the sense of pressure, heat, and moisture." (Howell.) In phimosis we have the three necessary conditions for local and general reflex irritation, heat, moisture and pressure, and absence of the squamous epithelium which should protect the nerve plate endings.

The vesicles being anatomically placed in the path of these sexual nerve stimuli, peripheral and central, can through emotional activity become congested, inflamed, distended by catarrhal secretion with pro-

*Read before the Medical Society of Newport, R. I., September 22, 1912.

duction of new connectitve tissue, final sclerosis and arrest of all stimuli ending in impotence. During this process of active irritation there is referred to the mind, abnormal, compelling excessive sexual impulses accompanied with melancholia and a deep suicidal desire. The moral control being lost, the victim becomes a blind prey to a force which has recently been called autonomic, whose victims I venture to say can be found in many prisons and sanatoriums, and may be the cause of many unexplainable suicides.

Etiology: Seminal vesiculitis is usually due to gonorrheal infection, phimosis, partial or complete, prolonged continence, influenza, typhoid fever, tuberculosis, colon bacilli, etc. The usual nervous symptoms are depression, lack of interest in occupation, horrible dreams, melancholia, with suicidal impulses, queer phobias, as a desire to jump off boats or bridges, or suddenly to leave theaters or churches in a state of panic. Whether these phenomena are mechanical from local vesicular irritation or distention, or, whether the chemically changed vesicle content contains toxins which by dialysis escape into the blood stream and pervert the function of cortex cells, I am not prepared to prove. Experience leads one to suspect some such process.

Diagnosis: Encouraged by the original surgical work and brilliant results of Dr. Eugene Fuller, the courtesy of whose clinic was kindly extended to me, clinical and private cases of a functional nervous type were studied and treated from the viewpoint of an internist. In a large number examined, chronic catarrhal seminal vesiculitis was present, often accompanied by partial or complete irritating phimosis. As regards the toxic nature of the vesical secretion, the absence of laboratory proof, is regretted as very little work has yet been done on this subject. Dr. Fuller's recent paper says: "Dr. Larkin, pathologist to the City Hospital, in making cultures from smears from this region, found uniformly the streptococcus in some cases of a peculiar reddish or pink hue." Dr. Crowe, working independently on arthritis deformans reports: "Out of twenty-two cases of rheumatoid arthritis nineteen were almost certainly infected by the *Staphylococcus aureus*. This coccus appears in Fleming's medium as a rose-red colony which gradually increases in size and deeply indents the medium,—on subculture it maintains these characteristics and does not alter in color."

When the finger is passed over the prostate gland and still further pushed on to the seminal vesicles above, pressure gives no pain under normal conditions, but when inflamed, the distress is peculiarly excruciating. Some patients suddenly collapse under the mildest manipulation. This condition and a history of the complex nervous symptoms associated should make a diagnosis comparatively simple.

Treatment: According to Dr. Fuller, the treatment of the sclerotic stage of vesiculitis, with arthritic complications, requires incision and drainage as originally devised by him. The treatment of catarrhal vesiculitis consists in (1) circumcision to relieve pressure, give vascular freedom and growth, and to promote normal squamous protection; (2) a careful series of strippings to free congestion and unload secretion every fifth day for several months. Under this treatment I have observed complex mental symptoms as well as manipulative local distress disappear simultaneously.

Case I.—History of an illustrative case. This patient was a physician, 48, bachelor, with a perfectly negative history, living a continent life. He had an unusually healthy inheritance. When a medical student it occurred to him that he had an ill-fitting prepuce and so consulted his surgeon-teacher who gave the usual advice: "You need nothing done; you can get that back for cleanliness." He dismissed the idea, and carried out the instructions. Perfectly healthy and progressive, still he was often reminded by friends of his high tension and marked self-consciousness. Several years ago an attack of acute cystitis followed sleeping in damp surroundings, which, in the absence of all other causes, undoubtedly originated in an exacerbation of an unrecognized chronic seminal vesiculitis. After six weeks, however, he was well again, with the exception of mild nervous "panics" that annoyed him. Sometimes in a train, or in a boat, if the motor stopped, an impulse to jump off would require great effort to control and conceal. In church a similar impulse was very marked. This condition lasted about one year, when during a slight anxiety in his affairs he became very nervous and sleepless. There were phobias, depressions, and horrible dreams which compelled resort to the restricted life of a sanatorium. His general health remained good, his face continued flushed, and he became very fat and flabby. There was no prostration or temperature. Some toxins do not cause temperature. If the bowels were constipated there was intense pain as the feces passed over the vesical region. He also had attacks of reflex pain simulating those of acute appendicitis. Hallucinations occurred, as in any case of profound infection. The possibility of a physical cause for all this was evidently not considered. He received the regular bed and board institutional care of obscure cases. Being a physician, he insisted that his trouble was reflex from a phimosis or possible vesiculitis demanding surgical interference. This was denied by the physicians of the institution. Their fears of further aggravating the nervous symptoms unfortunately served only to prolong his period of confinement. The patient remained in this condition for two years, eventually regaining enough stability to reach New York. He was by no means well, the journey having been a constant struggle between impulse to jump and an effort to control. Within an hour after his arrival, on his own initiative, a consultation with a genitourinary surgeon was held. A prepuce sufficiently tight to destroy epithelial growth, deform the glans, and arrest development was discovered, accompanied by chronic seminal vesiculitis. Circumcision to be followed by vesicle massage was immediately advised.

Instant relief of nervous tension followed the first operation, while massage with the escape of half an ounce of secretion made a most striking change in his mental symptoms. He was at once a different man. A curiously ravenous desire for meat followed for one week. Stripping of the vesicles was repeated every fifth day for five months and proved an interesting and convincing performance. He gradually lost the fullness of the head, capillary flush, and mask-like feeling in the face. The fear of elevators, bridges, crowds, and theaters, and the terrible dreams all slowly disappeared, and with them twenty pounds of accumulated adipose. In six months he expressed himself normal physically, sexually, and mentally, with a mental cheer and poise that was as new as it was delightful. It is interesting to note that when the sexual function was not exercised, the terrible dreams returned, but eventually disappeared. An early diagnosis that would have saved this physician his health, his practice, and a great monetary loss should have read: (1) Partial phimosis with reflex irritation. (2) Chronic catarrhal vesiculitis. (3) Toxic infection perverting the cells of cortex and general metabolic interchange. Prompt and complete physical diagnosis, including this region and treatment as above described, would have cured this case at its inception.

Case II.—The following is an account taken from the letter of a patient referred to me during the preparation of this paper. In reply to my request for a history he sent the following, which gives so well the career of these patients that I give it verbatim. "In compliance with your request, I am sending you my history, dating back to 1904. At that time I became very nervous and irritable. I complained to my doctors of the general bad feeling, weak and nervous, and could not keep still, could not sleep. They gave me the usual tonics and sleeping mixtures with no result. I was a driver on a fire engine, but gave up my position, consulted three specialists. It was decided I should

take a long rest. I went to the woods for several months; came back worse. I was advised again to go to a camp; remained for six months; not much gain; returned and saw a noted specialist. His decision was—no brain trouble at all; simply nerves. Advised sanatorium life; remained there from October until spring; still no improvement. I committed myself to a State Hospital for the Insane; they decided I was not insane, but self-centered. Remained here a short while, and I left for the woods again for the summer, but did not improve. Returned to the sanatorium; remained three months; then advised to go to camp again. Here I remained for the past four years. Then entered a psychopathic hospital for seven weeks; had two blood tests and a lumbar puncture, both negative. Opinions of neurologists varied from locomotor ataxia, change of life, over ambition, self-centered, too much head work, poor nutrition, too much fire department strain with reckless driving, etc.; too much women and booze; but last, and best of all—I don't know—it's a funny case; I wish I did. I paid out in all over $5,000 during these years in camps and doctor bills and can't see where I have gotten any benefit other than to be alive."

A complete physical examination located the cause of this purely reflex and functional irritation in the seminal vesicles. Appropriate treatment was instituted and after five treatments he writes he finds himself more capable of concentration, very much less nervous, and on the road to recovery.

Case III.—A Wall Street business man, age 40, married, gonorrhea at 18, came for diagnosis November 18, 1913. Five years ago had severe attack of neuritis, occasional attacks since. Complains of indigestion and bloating of intestines. Chronic constipation, depression, dizziness, and loss of control, sometimes on the street and at his desk. Six months ago the depression became more marked; he became alarmed, giving up his business temporarily; went camping for four months. His general health improved some, but he was still melancholy. Physical examination negative except distention of abdomen and severe pain on deep pressure over appendix region. Seminal vesicles enlarged, congested, and extremely sensitive. Blood and urine normal. Reflexes normal. Diagnosis: Chronic catarrhal seminal vesiculitis involving the appendix region. After the second treatment of the vesicles depression disappeared, the bowels became normal in action and appearance; constipation was relieved. After seven treatments, he is now perfectly well, all these symptoms are gone, including the neuritis and tenderness at the appendix area. He has gained five pounds in weight; his expression and mental view changing from a gloomy outlook to one of normal hope and cheer.

Conclusions: (1) The advantage of circumcision should be given every male infant. (2) Stretching of the orifice as some advise is vicious. (3) Adults presenting the complex nervous symptoms above described, even in a mild way, should have the sexual region carefully examined for painful seminal vesicles. (4) Notwithstanding the advice of an eminent American authority who says, "Rectal examination is not and should not be a part of a physical examination," internists should be able by digital examination, to distinguish between normal and painful vesicles, for at this point a man's honor, marital happiness, character, good citizenship, and even his freedom may depend.

Without experience it is difficult for us to refer functional nervous and mental symptoms to such an obscure source. Many times, however, relief comes only by surgical drainage or proper manipulative treatment of these hidden secretory organs.

78 East Fifty-fourth Street.

**Scarlet Fever as a Reaction of Sensitization.**—F. v. Szontagh advances the theory that the clinical manifestations of scarlet fever are the result of an increased susceptibility of the body resulting from disturbances in the alimentary tract. In other words, scarlet fever represents one of the forms of alimentary anaphylaxis.—*Jahrbuch für Kinderheilkunde.*

## Medicolegal Notes.

**Practising Without License—"Chiropractics."**—A complaint charged the defendant, who held himself out as a "chiropractor," with practising medicine without a license in violation of Rhode Island Gen. Laws, 1909, c. 193, § 8, making the offence a misdemeanor. It appeared from the testimony that the defendant had received an elementary education, had been employed as bricklayer and mason, had, eight years before, attended for three or four months a school of chiropractics in Minnesota, and thereafter set up a business as a chiropractor, issuing pamphlets in which he professed to "adjust the causes of disease without drugs, based upon a thorough knowledge of the nervous system." He was careful to avoid the use of the word "cure," and in his defense he undertook to exclude himself from the practice of medicine by showing that he did not take the pulse or ascertain the temperature of the patient, did not administer drugs, and did not otherwise employ the means usually resorted to by physicians in aid of their diagnosis. He claimed that the chiropractic idea was not to cure the disease, but to remove the cause, and thus allow or bring about a recovery therefrom. The court, however, did not admit the distinction, and found the defendant guilty, holding that the practice of medicine or surgery in itself does not require the administration of drugs.—Swarts v. Sweny, Rhode Island Supreme Court, 85 Atl. 33.

**Degree of Skill Required.**—In an action for neglecting to properly diagnose a fracture of the neck of the left femur, and for unskillful and negligent treatment, the court stated the settled law as being that a patient who employs a physician is entitled to a thorough and careful examination, such as the condition of the patient and circumstances will permit, with such diligence and methods of diagnosis for discovering the nature of the ailment as are usually approved and practised by medical men of ordinary learning, judgment and skill, in similar localities. If by the exercise of such care and skill the fracture would have been discovered, a failure to properly diagnose is negligence, and it is the duty of a physician, in taking charge of a case where there is a broken limb, to inform and instruct the patient as to his conduct and what caution should be observed in moving or using the limb while it is being treated. In such an action expert testimony is admissible on the question whether the treatment and acts of the defendant were proper. What would constitute an injury to the plaintiff in such an action has been thus judicially defined: "Any want of the proper skill or care which diminishes the chances of the patient's recovery, prolongs his illness, increases his suffering, or, in short, makes his condition worse than it would have been if due skill and care had been used, would, in a legal sense, constitute injury."—Craig vs. Chambers, 17 Ohio St. 253.; Rogers vs. Kee, Michigan Supreme Court, 137 N. W. 260.

**Practising Without License—Individual Offenses.**—The Kansas statute provides that any person who shall practise medicine in that State without having received and recorded a certificate from the State board of registration and examination shall be deemed guilty of a misdemeanor, and upon conviction thereof shall pay a fine of not less than $50 nor more than $200 (Gen. Stats. 1909, § 8091). It is held that this section does not create a continuing offense involving a general course of customary conduct, but penalizes each specific act of practice defined in section 8090. "To prescribe, for a fee," said the court, "any drug for the relief of any disease of another person is to practise medicine. It is not necessary that this be done frequently, customarily, or habitually. One isolated instance is sufficient, and the penalty is affixed to each offense. The same is true of surgical operations and other specific acts denounced by the statute. Besides this, any fair consideration of the mischief which the Legislature sought to remedy leads to the conclusion that the State board of medical registration and examination was not created for the simple purpose of attaching its badge to professional careers. The life, health and financial resources of individual men, women, and children were to be protected from ignorance and imposture. Each act of unlicensed practice may be fraught with danger. Every repetition is a new peril, and, instead of applying to a continuous course of conduct, the statute specifies and condemns each impulse, to the very end that it may not unite with others in swelling a common stream of action."—State v. Cotner, Kansas Supreme Court, 127 Pac. 1.

## ABORTIVE SCARLATINA IN THE NEWBORN.

NEITHER the mode nor the source of infection in scarlet fever is as yet known, though there is a valid basis for the belief that in the majority of cases the throat is the portal of entry for the virus. Other mucous membranes besides that of the throat and also wounds occasionally furnish the avenue of infection. Leube provided a classical experiment in his own person while performing an autopsy on a patient who had died of scarlet fever. He cut his finger and eleven days later he showed the manifestations of scarlet fever, the rash beginning at the site of injury. The subject of relative immunity in scarlet fever is still veiled in obscurity. For instance, Martin reported the observation of three cases of scarlet fever among 16,000 puerperæ. One is not justified in concluding from this that the puerperium or pregnancy offers any protection against scarlet fever, for only 30 per cent. of all individuals are susceptible to scarlet fever, and of these the majority acquire the disease between the ages of seven and twelve years. It would therefore be rather exceptional for scarlet fever to develop during the puerperium.

An interesting study of this phase of the subject was made by Carl Levi of the Division of Infectious Diseases of the Rudolf-Virchow Hospital of Berlin. He reports his results in the "Beiträge zur Klinik der Infektionskrankheiten und zur Immunitätsforschung," Vol. 2, No. 2. He observed during the past few years the occurrence of scarlet fever in one gravid patient and in eleven puerperæ. The point of special importance in his investigation was the question of the relative immunity of the offspring of these patients; the newborn infants were intimately exposed to infection. Of extraordinary rarity is the occurrence of scarlet fever during the first three months of life. So far as the literature is concerned, it may be noted that among 1,041 cases of scarlatina Johannsen observed none during the first month of life, and 3 per cent. during the second and third months. Finkelstein states that scarlet fever is observed in infants at all ages, even immediately after birth, and that the disease in the very young runs a typical course. Of 3,603 cases of scarlet fever analyzed by Pospischill and Weiss there were only twenty-eight cases during the first year, and these had their incidence during the later months of the year. Levi had the opportunity of observing nine cases of scarlet fever in infants less than three months of age and one case in an infant nine months old. With the exception of the last, all were the infants of mothers suffering from scarlet fever.

The author distinguishes between two groups according to the course of the disease. The first group comprised three children of which two were bottle fed and one was breast fed. These three cases ran a typical course although they were mild and presented certain gaps in the symptom complex. The second group of cases comprised seven breast-fed infants in whom the disease was much less pronounced. The symptoms were so atypical that the diagnosis was made only by taking into account the immediately prior occurrence of scarlet fever in the mother. The clinical phenomena in all of these cases were somewhat as follows: from three to seven days following the onset of the disease in the mother the infant took sick with a moderate fever lasting from two to four days. There was the characteristic tongue with the reddening of the tonsils and of the soft palate. In no instance was there any membrane on or necrosis of the tonsils. There was at first some difficulty in nursing and a disinclination to take the breast. In two of the cases a fugitive scarlatiniform eruption was observed. In the remainder of the cases the occurrence of desquamation proved that the infant had had scarlet fever. Likewise the occasional occurrence of adenitis or otitis, and in one instance a transient albuminuria clinched the diagnosis. The mild course of the disease and the mildness of the separate symptoms apparently justified the author in regarding these cases as instances of abortive scarlet fever. The mildness and rapid course of the disease may account for the fact that similar cases may have been largely overlooked in the past. It is pointed out that in the cases of the breast-fed children the disease ran a much lighter course than in those that were bottle fed. This may be a fact of some significance. The question now arises: Why does scarlet fever run such an extraordinarily mild course during the first few months of life? It may be supposed that in the newborn of mothers who have recently had scarlet fever, there are transmitted to the infant from the mother antibodies that impart a more or less complete immunity against scarlatinal infection. This hypothesis is strengthened by the observation that patients who develop scarlet fever during the puerperium transmit only an abortive type of the disease to their offspring. It is quite conceivable that in these instances the antibodies reach the child through the milk, analogous to the cases in which salvarsan is administered to the child by way of the mother.

As the result of his studies Levi reaches the following conclusions: Infants during the first few months of life have no special immunity with respect to scarlet fever. Nevertheless, in the case of the newborn of mothers who have recently had an attack of scarlet fever the disease runs a mild and abortive course. Puerperæ who have been exposed to scarlatina acquire the disease as readily as do others belonging to the same period of life.

## EARLY OPERATION IN CASES OF UTERINE FIBROIDS.

THE passive or expectant attitude was formerly quite generally observed with regard to the treatment of uterine fibroids, though of late not a few voices have been raised in favor of early operation. In the *Medical Press and Circular*, Feb. 18, 1914, Arthur E. Giles makes a fresh plea for early operation in such cases. He states that the possible reasons for the expectant method are: (1) That at the menopause the symptoms disappear and the fibroids tend to shrink. (2) That fibroids are not dangerous tumors. (3) That operation is attended by a high mortality insomuch that the risk of operation is greater than the risk of leaving things alone; and that years of invalidism and disability are preferable to running the great risk.

Giles thinks that the first of these reasons is based on a succession of fallacies. One of these is the assumption that the only bad symptom of fibroids is hemorrhage. Hemorrhage is only one symptom, and moreover it is a symptom in only some kinds of fibroids. The other symptoms, pain, pressure effects, disability, and general weakness, are not improved by the menopause and may be aggravated. The assumption that hemorrhage caused by fibroids is only menstruation, is one that could be excused only if made by a layman. The argument that fibroids shrink after the menopause will not bear looking into. Giles points out that in many cases they actually increase in size and in the few cases where a shrinkage occurs the effect may be worse than it was before, as a fibroid that lodged previously above the pelvic brim may become impacted in the true pelvis.

As for fibroids not being dangerous tumors the same may be said of ovarian tumors, the dangers of which lie in their possible complications. In the same way, the danger of fibroids, apart from the draining effects of hemorrhage, lies chiefly in their possible complications. Moreover if it could be truly said that ovarian tumors are dangerous but fibroid tumors are not, there still remains the question: Can we be sure, in any given case, that the tumor is a fibroid? Finally the argument based on the high mortality of operation would have had great weight 25 or even 20 years ago; this mortality has dwindled with the progress of abdominal surgery, and hysterectomy may now claim a recognized place, not only as an operation for saving life, but as a means for relieving suffering.

The author's reasons for early operation are as follows: (1) The age incidence of fibroids is so varied that no importance can be attached to age as an indication for operation. (2) Early operation would often allow of a conservative myomectomy, whereas delayed operation necessitates hysterectomy. (3) In a large proportion of cases fibroid tumors are associated with pathological complications, many of which are of a dangerous nature. (4) Diagnosis is still so uncertain that grave conditions urgently requiring operation may be mistaken for simple fibroids. (5) The mortality attendant on the procedures of myomectomy and hysterectomy in the practice of experienced surgeons has become so reduced that operation may legitimately be advised for the relief of suffering, even when life is not directly threatened.

## REFRIGERATION IN THE PRESERVATION OF FOOD.

IN these days when cold storage, the employment of preservatives in foods, and the adulteration of food products are being subjected to the most severe criticism, a discussion held by the Society of British Medical Officers of Health on the refrigeration of food, and reported in the *Lancet* Feb. 28, should prove of interest. Dr. Hanna, who opened the discussion, referred to the fact that the United States was not only no longer sending cattle to Great Britain but was taking for its own supply cattle from countries which had hitherto exported almost exclusively to Great Britain. He went on to point out that the methods of refrigeration of foodstuffs depended chiefly on the scientific fact that expanding air or vaporizing substances, such as sulphurous acid, carbonic acid, or ammonia, in assuming the gaseous form abstracted heat from the atmosphere or other bodies in the neighborhood. Fresh meat was carried from distant countries either as hard frozen meat or chilled meat. Chilled meat arrived in a condition ready for consumption and retained the characteristics of fresh meat more closely than frozen meat, but the chilling process required great care, and the transport needed constant supervision. The frozen method was the better as regarded preservation, although it sometimes damaged the cellular and fibrous structure of the meat unless special care was taken in defrosting. Hanna gave it as his opinion that frozen meat when thawed would keep with proper care as well as freshly killed meat after being taken from the refrigerator, even in high temperature, a view not in accordance with popular opinion.

Hanna considered that refrigeration afforded a ready means of obtaining a plentiful and cheap supply of food, and he thought that every means was now being taken to obtain and keep the supply wholesome by the constant attention of the producer abroad to the methods of inspection and handling and by its thorough examination on landing in England. Sir Shirley Murphy, who joined in the discussion, spoke of the effect of cold storage on the flavor of meat, and thought that the process might even improve the flavor. Of course refrigeration or chilling of foodstuffs is necessary when these have to be conveyed for long distances, as for example from North or South America to Europe, but great care must be exercised both in the process itself and the defrosting. That, however, animal food thus treated does not undergo a certain amount of deterioration is a view opposed, at least, to popular ideas, and certainly Murphy's suggestion that refrigeration may improve the flavor of meat is one not borne out by experience. It might be in the interests of the consumer if scientific investigations were carried out to show exactly what effect refrigeration has upon animal food and for how long a period meat can endure the process without undergoing harmful changes.

### The Rôle of Climate in the Therapy of Tuberculosis.

A great deal of uncertainty still exists as to the exact rôle which climate plays in the treatment of tuberculosis. It is unfortunate that most practitioners cannot dispel this uncertainty and that tuberculous patients are frequently sent to climates that are not particularly well suited to their individual cases. The patient, particularly if he has financial means, desires to be sent to a climate that offers him the greatest advantages, but as is pointed out by G. Schröder and A. V. Müller in the *Zeitschrift für Tuberkulose*, February, 1914, this quest of the ideal climate is like the pursuit of a phantom. Every climate possesses certain advantages and at the same time certain disadvantages. The physician in considering the adaptability of any place should take into account not only the sum total of its meteorological factors, but also its other characteristics which may have some important effect upon the progress of the patient's treatment. Schröder has for a long time maintained that there is no climate that acts as a specific in tuberculosis. Climate can act only as an adjunct in the management of any case. Inland or mountain, seashore or farm, may be adapted for a particular type of case. In order to form a correct idea of the suitability of any health resort it is necessary not only to know its geography and meteorology, but also to understand its entire milieu. The advantages of a sanatorium with its discipline and regularity far outweigh those of a most salubrious climate without these factors. The authors made a comparative investigation of seven well-known climatic resorts with respect to their adaptability in tuberculosis. They selected as their type-climates for comparative studies the following places: Wyk on the island of Föhr, a cool and damp sea climate; Schömberg and Neuenbürg in the Black Forest, at a moderate mountain elevation; Frankfort-on-the-Main, noted for its sunshine and low elevation; Nice and the Riviera, a dry warm sea climate, and Davos, high up in the mountains. They found that each of these places has its advantages at certain times in the year. They found above all that central Europe provides no optimum climate for tuberculosis, but that its different resorts have certain advantages the wise selection of which may be utilized in the treatment of tuberculosis.

### Origin of Syphilis.

In speculating upon the first appearance of a disease, it is clearly important to begin with the alleged date and circumstances accompanying the origin of the affection and then go back a few years at a time, as well as go forward similarly, in order to see if the legend concerning the new malady will hold water. Diepgen, a leading antiquary of Germany, recently read a paper before the Freiburg Medical Society (*Berliner klinische Wochenschrift*, Feb. 2) which was largely a review of some recent work on the origin of syphilis by Sudhoff and others. The legendary view of this subject is that the disease broke out in Italy in 1495 in connection with the Charles VIII invasion. Diepgen adduces the following established data to the contrary: First, as far as the term "French disease" is concerned (the first name of syphilis), this is known to have existed before that date (he might have said for many years); Second, no actually contemporary documents mention a Spanish-American origin of syphilis; Third, the histories of alleged endemics of syphilis in Naples in 1495 are purely late interpolations; Fourth, the legend of a sudden general widespread outbreak of syphilis over Europe is not supported by facts. Hence there was no original virgin soil to favor the rapid, intensive development of a new disease; Fifth, French barbers, surgeons, and prostitutes knew of the disease and its transmissibility by sexual intercourse before 1490.

## News of the Week.

**City Death Rate.**—For the week ending March 28, the death rate in New York was 16.52 per 1,000 of population, or 0.4 higher than during the corresponding week of last year; the total number of deaths for the week was 1,768. The death rate for the first thirteen weeks of 1914 was 15.60 per 1,000, against 15.86 for the same period of 1913.

**Tons of Food Destroyed.**—During the year 1913 the New York City Department of Health destroyed more than 13,000,000 pounds of bad food. Constant supervision was maintained over more than 2,700 establishments where food of various sorts is prepared or vended, arrests to the number of 3,200 were made, and fines amounting to $3,200 imposed.

**Changes in the Health Department.**—Dr. William T. Jenkins, physician to the Willard Parker Hospital, Dr. Joseph Creamer, physician to the Riverside Hospital, and Dr. Cyrus J. Strong have resigned their positions, and their resignations were accepted by the Board of Health at a meeting on March 31. At the same time Dr. Haven Emerson, whose selection was announced last week, was appointed Sanitary Superintendent in the Department. The Board also created an Advisory Council to the Department of Health, which is to be subdivided into committees corresponding to the several departmental bureaus, and the following chairmen of these committees were announced: Dr. Lee K. Frankel, public health education; Dr. John H. Huddleston, infectious diseases; Prof. C.-E. A. Winslow, sanitation; Dr. Louis I. Dublin, records; Dr. Simon Flexner, laboratories; Homer Folks, child hygiene; Bailey B. Burritt, food inspection.

**Georgia Medical Society.**—The new home of the Georgia Medical Society at 612 Drayton Street, Savannah, the culmination of the united efforts of the medical profession of Savannah, was formally dedicated and delivered to the Society on the evening of March 31. The key to the building was presented by Dr. T. J. Charlton, chairman of the home committee, to Dr. J. L. Jackson, president of the society, who in accepting said that the opening of the home marked an epoch in the history of medicine in Savannah and Georgia. The address of the evening was delivered by Dr. J. Ewing Mears, honorary member of the society, who has established the Mears Foundation Library of the society. Dr. Mears referred to the long list of men who as members of the Georgia Medical Society had brought honor to it during its life of more than a century and whose names were bound up with its history and the history of the medical profession in Georgia. The Georgia Medical Society, he pointed out, having been incorporated in December, 1804, is the oldest medical association in the South and one of the oldest in the country. Its organization, as stated in the act of incorporation, was for "the

purpose of lessening the fatality induced by climatic and incidental causes and improving the science of medicine, and in order to insure and establish the said institution in a permanent and effectual manner so that the benevolent and desirable objects thereof may be executed with success and advantage." The illustrious founders of the society had thus transmitted a sacred trust, which Dr. Mears called upon the present members to pass on to their successors with its honor untarnished.

The new home of the society is in colonial style, with the assembly hall and the library on the main floor. The two floors above this will eventually be used for an extension of the library and for a research laboratory, but for the present have been fitted up as living apartments.

**Syracuse University Dispensary.**—The new dispensary building of the Medical College of Syracuse University, Syracuse, N. Y., was formally opened on March 30, 1914. The building has been carefully designed and is believed to meet every requirement of a dispensary. On the first floor there are the offices, pharmacy, and clinic rooms; on the second floor, clinic rooms; on the third, laboratories, and in the basement an *x*-ray room, milk distributing station, orthopedic shop, and manufacturing pharmacy. At a public meeting on the evening of the same day the building was turned over to the Syracuse Free Dispensary Association, which will continue its operation, while vesting in the Faculty of Medicine of the University the organization and administration of the medical and surgical service. The address of the meeting was made by Dr. Richard C. Cabot of the Harvard Medical School, Boston.

**Surgeon-General Gorgas.**—After three months spent in South Africa in the investigation of the epidemics of pneumonia among the native miners in the Rand district, Surgeon-General Gorgas returned to New York on April 1.

**Study of Animal Diseases.**—The Rockefeller Institute for Medical Research, New York, announces that it has received from Mr. John D. Rockefeller an additional endowment of $1,000,000 for the purpose of organizing a department for the study of animal diseases. A pledge of $50,000 has also been received from Mr. James J. Hill, the money to be used in the study of hog cholera. The announcement says: "It is the expectation of the trustees of the institute that the new department by making possible a very thorough and exhaustive study of animal diseases by trained experts will prove a great boon to raisers of cattle, hogs, sheep, and other animals, as the opinion has been expressed that many of the diseases could be held in check and perhaps practically stamped out if the breeders had practical knowledge on which to act. With the present facilities at hand, the income from the $1,000,000 endowment will make it possible to carry on the work on a broad scope at once."

**American Posture League.**—Under this title an organization aiming to prevent round shoulders and aching spines was incorporated at Albany, N. Y., on March 31. The directors are: Jessie H. Bancroft, New York, *President;* Dr. Frederick R. Green, Chicago, *First Vice-President;* Dr. Joel E. Goldthwait, Boston, *Second Vice-President;* Cornelius S. Loder, New York, *Acting Treasurer;* Dr. Henry Ling Taylor, New York, *Secretary;* Dr. E. G. Brackett, Boston; Dr. S. Josephine Baker, New York; Dr. William H. Burnham, Clarke University; Dr. Eleanora S. Everhard, Dayton, O.; Dr. R. Tait McKenzie, Philadelphia; Dr. Eliza M. Mosher, Brooklyn, and Dr. Thomas A. Storey, New York.

**Street Accidents.**—Twenty-seven persons were killed by vehicular traffic in the streets of New York during the month of March. Of these, 12 were killed by automobiles, 7 by street cars, and 8 by wagons. Fourteen of the killed were children. Forty-three persons were injured by automobiles, 29 by street cars, and 12 by wagons. The records of the first quarter of the year, as compared with the same period last year, show a falling off of 22 per cent in street car accidents, 10 per cent. in automobile accidents, and 25 per cent. in wagon accidents.

**Surgical Clinics.**—During the week of the meeting of the International Surgical Congress in New York the following special lectures and clinics will be given for the general medical public at the New York Polyclinic Medical School and Hospital, 341 West 50th street:

April 14, 11 A.M. to 1 P.M. Internal Photography as an Aid to Diagnosis. Alfred C. Jordan, M.D. Cantab., M.R.C.P., Medical Radiographer, Guy's Hospital, London.

April 15, 11 A.M. to 1 P.M. Hypothyroidism. Lecture and demonstration with stereopticon pictures. Dr. E. Hertoghe, Member of the Royal Academy of Medicine, Belgium.

April 16, 11 A.M. to 1 P.M. Surgery of the Heart and Lungs. Lecture and demonstration. Benjamin Merrill Ricketts, M.D., LL.D., Cincinnati, O.

April 17, 11 A.M. to 1 P.M. Treatment of Fractures. Clinic and demonstration. Dr. Albin Lambotte, Surgeon-in-chief, Stuivenberg Hospital, Antwerp.

**Lecturer on Tropical Medicine.**—Captain Arthur N. Trask, Medical Corps, U.S.A., has been appointed lecturer on tropical medicine in the Long Island College Hospital, Brooklyn. This is a new department recently established at the medical school.

**Scarlet Fever in New Jersey.**—Scarlet fever is reported to be prevalent in many of the towns in New Jersey in the vicinity of Trenton and Bordentown. A large number of cases have been reported and several deaths have occurred. An outbreak of diphtheria at Pemberton, in addition, has caused alarm, and the schools there have been closed, and church services discontinued. In Bordentown it has been found advisable to close the moving picture theaters as well as the schools for two weeks.

**Bronx Hospitals.**—As the results of recent investigations the Grand Jury of Bronx County, New York, on March 31, handed to Supreme Court Justice Brady a presentment calling attention to the inadequacy of hospital accommodations in the borough. It is recommended that a pest house be built immediately, that Fordham Hospital be enlarged, that all ambulance services be autovehicular, and that the control of the administration of the hospitals be centered in one department or board instead of at present being under the control of different departments. As a result of this presentment steps are being taken to hasten the construction of a new Bronx Hospital, which has been under consideration for some time.

**Gifts to Charities.**—By the will of the late Margaret A. May of Philadelphia the sum of $5,000 is bequeathed to the Episcopal Hospital of that city for the endowment of a free bed. The hospital will

also receive a considerable portion of the residuary estate, the value of which has not been determined.

The Danbury Hospital, Danbury, Conn., receives a bequest of $1,500 by the will of the late Mrs. Julia E. Ferry of Bethel, Conn.

The Royal Victoria Hospital, Quebec, has received from Mr. James L. Ross an offer of a sum sufficient to erect a private pavilion of 150 beds, to be known as the Ross Memorial Pavilion in remembrance of the donor's father, Mr. James Ross. It is estimated that the cost will be between $250,000 and $300,000.

The endowment of three free beds in St. Luke's Hospital, New York, is provided for in the will of the late Mrs. Mary D. Lane, who set aside $15,000 for the purpose.

By the appraisal of the estate of Ferris S. Thompson, who died in Paris last year, the value of the bequests to various charitable institutions have been determined. Mercy Hospital, Chicago, receives $229,155; the New York Skin and Cancer Hospital, $101,753; the Woman's Hospital, New York, $83,581; St. Luke's Hospital, New York, $39,620, and the American Hospital, Paris, $25,000.

By the will of the late L. A. Van Praag of New York $5,000 is left to Columbia University to be used for research work into the causes and cure of cancer. Other bequests are $1,000 each to St. Rose's Free Home for Incurable Cancer and the Montefiore Home.

**Island Hospital.**—Commissioner Davis of the Department of Correction of New York City is having plans prepared for the erection of a new hospital building on Blackwell's Island for the penitentiary inmates. The new building will be placed to the south of the penitentiary, where it will be open to the sunlight and fresh breezes from the river. The present hospital will probably be continued in use as a dispensary for the treatment of minor prison cases.

**Tuberculosis Hospitals Needed.**—In commenting on the work which has been accomplished during the last three years, a recent report of the Committee on the Prevention of Tuberculosis of the Charity Organization Society, calls attention to the need of greater hospital facilities for tuberculosis patients in New York. It states that the records of the Health Department show 40,000 such patients in the city, the majority living in tenement houses, with only 3,051 hospital beds provided, and declares that the overcrowded condition of the hospitals is a disgrace to the city. That the tuberculosis campaign is beginning to prove effective, however, is shown by figures quoted from a recent bulletin of the Health Department. The death rate from pulmonary tuberculosis in New York City was 2.25 in 1898, and 1.66 in 1912; the total number of deaths being 7,724 in 1898 and 8,591 in 1912.

**Memorial Service.**—Students and members of the Faculty of the University and Bellevue Hospital Medical College held a service on April 4 in memory of Dr. Egbert Le Fevre, dean of the college, who died on March 30. The chancellor of the university, Dr. A. A. Smith, Dr. George D. Stewart, and others spoke of the esteem in which Dr. Le Fevre was held and the valuable work he had done during his long connection with the college.

**Lives To Be 120.**—Bias Casanova, said to have been the oldest man in Cuba, died on April 4 at the reputed age of 120 years.

**Clinic for Peddlers.**—The Department of Health has announced that hereafter all applicants for licenses to peddle from pushcarts will be examined at the tuberculosis clinics and that preference in granting the licenses will be given to those who will apparently be benefited by the outdoor work.

**Yellow Fever in Ecuador.**—Sixteen cases of yellow fever have been reported in Esmeraldas and the disease is said to be spreading through the country.

**Medals Bestowed.**—Dr. Charles C. Bass, Dr. Charles W. Duval, and Dr. A. L. Metz, all members of the faculty of the Medical Department of the Tulane University of Louisiana, received medals from the American Institute of Social Science at a meeting held in the City Hall of New Orleans on March 14.

**In Memory of Dr. Mitchell.**—A memorial meeting in honor of the late Dr. S. Weir Mitchell was held on the evening of March 31 in Mitchell Hall of the College of Physicians of Philadelphia, under the auspices of the College, the University of Pennsylvania, Jefferson Medical College, the Library Company of Philadelphia, and the Academy of Natural Sciences. Following some introductory remarks by Dr. J. C. Wilson, addresses were made by Dr. Talcott Williams, director of the School of Journalism, Columbia University, who spoke of Dr. Mitchell as a man; by Dr. William H. Welch, Johns Hopkins University, who was present as the representative of the National Academy of Science and of the Carnegie Institution of Washington, and who spoke of Dr. Mitchell as a physician and man of science; and by Owen Wister, the novelist, who spoke especially of the literary career of Dr. Mitchell and pointed out the debt owed to him by American literature.

**Obituary Notes.**—Dr. Everett Herrick of New York, a graduate of the Jefferson Medical College, Philadelphia, in 1864, and a member of the American Medical Association and of the New York State and County Medical Societies, died at his home after a long illness, on April 1, aged 85 years.

Dr. Payson Jonathan Flagg of Mittineague, Mass., a graduate of the Jefferson Medical College, Philadelphia, in 1885, and a member of the Massachusetts and Hampden District Medical Societies, died at his home, after a short illness, on March 22, aged 55 years.

Dr. John Alexander Fitz-Hugh of Amesbury, Mass., a graduate of the Cleveland, O., Medical College, in 1880, and of the Hahnemann Medical College and Hospital, Philadelphia, in 1881, a member of the Massachusetts and Essex District Medical Societies, and vice-president of the latter, died at his home on March 21, aged 60 years.

Dr. George Parker Williard of Tiffin, O., a graduate of the Jefferson Medical College, Philadelphia, in 1867, a veteran of the Civil War, and a member of the Ohio State and Seneca County Medical Associations, died at his home, from pneumonia, on March 20, aged 68 years.

Dr. Albert Waldo Forbush of Somerville, Mass., a graduate of Eclectic Medical College of the City of New York, in 1881, died at his home on March 20, aged 62 years.

Dr. Edgar de Mott Stryker of Holkol, Corea, a graduate of the College of Physicians and Surgeons, New York, in 1901, formerly a resident of Pine Bush, N. Y., but for the past five years head of the hospital of a large mining company at Holkol, was shot and instantly killed by a Japanese supposed to be crazy, on March 29, aged 40 years.

## Obituary.

### JOSEPH DECATUR BRYANT, MD., LL.D.

NEW YORK.

Dr. Joseph D. Bryant, whose death occurred on Tuesday of this week, was a man of wide learning and broad human sympathies and had led a life of great professional activity and of usefulness in many and varied directions. He had been Surgeon General of New York State, Health Commissioner of New York City and Commissioner of the State Board of Health; president in succession of the New York Academy of Medicine, the New York State Medical Association, the New York State Medical Society, and the American Medical Association. He was a member of the International Society of Surgeons and of the American Surgical Association. He was also a veteran of the Seventy-first Regiment of the National Guard, and was for several years the Surgeon Major of that command. He was at one time President Cleveland's physician and for many years enjoyed his friendship and confidence.

Dr. Bryant was born in East Troy, Wis., on March 12, 1845. He was educated at Norwich, N. Y., and obtained his medical degree from the Bellevue Hospital Medical College in 1868. He spent two years as interne in Bellevue Hospital, and ever since that time had been connected in one capacity or another with the faculty of the Bellevue Hospital Medical College and of its successor, the University and Bellevue Hospital Medical College, holding the chair of the principles and practice of surgery and of clinical and operative surgery in the latter institution at the time of his death. He was a visiting surgeon at Bellevue Hospital since 1882 and at St. Vincent's Hospital since 1887. He was also consulting surgeon to the New York City Insane Asylum, the Northwestern Dispensary, Hospital for the Ruptured and Crippled, Woman's Hospital, and St. Joseph's Hospital, Yonkers. He contributed frequently in his earlier days to the medical periodicals, was the author of a treatise on Operative Surgery in two volumes, and was co-editor with Dr. Buck of the American Practice of Surgery in eight volumes.

---

At a special meeting of the Medical Board of St. Vincent's Hospital, held on April 8, 1914, the following minute was adopted:

"Whereas: It has pleased God, in the infinitude of His Mercy, to remove from his sphere of usefulness in this community, Joseph Decatur Bryant, M.D., LL.D., for twenty-seven years Visiting Surgeon to this Institution; therefore, be it

"Resolved: That in the death of Dr. Bryant, St. Vincent's Hospital has lost an officer whose great surgical skill and vast experience has always been at the service of its sick and suffering poor; the Sisters in charge have lost a loyal friend and wise counsellor; and his colleagues have lost an inspiring example of duty and a genial companionship difficult to replace.

"Resolved: That a copy of these resolutions be spread upon our minutes, and that copies be sent to the public and medical journals, and a copy be sent to the family of deceased."

José M. Ferrer, President.

Charles Edward Nammack, Secretary.

## Correspondence.

### OUR LONDON LETTER.

(From Our Regular Correspondent.)

CAMBRIDGE MEDICAL SCHOOL—MEDICINE OF 14TH CENTURY—SOLDIERS' DAUGHTERS' HOME INVADED BY DIPHTHERIA—HOSPITAL SOLD—KING EDWARD'S HOSPITAL FUND—FOTHERGILL MEDAL—PROPOSED MEDICAL SCHOOL FOR WALES—FOUNTAIN A DISEASE CARRIER—OBITUARY.

London, March 20, 1914.

The appeal for State aid for all sorts of objects is so common and so urgent that it seems to give one a novel sensation to hear of the offer of such assistance exciting fierce objection. Yet a heated discussion has for some time been carried on in Cambridge University as to whether the Medical School should be allowed to accept the offer of money granted by parliament, and on Saturday a poll was taken with the excitement of a political election. Permission was given by 268 to 235, a majority of 33 for the medical school. To summarize the dispute, I should tell you that the Board of Education has at its disposal funds from which it makes grants in aid of work in the universities and colleges in connection with medicine. The other universities and nine out of eleven medical schools in London enjoy such grants. The Cambridge Medical School, which claims to be the largest in England, is straitened for income and needs help to keep abreast with the times, maintain the efficiency of the school and promote research. Accordingly, request was made to the University to apply to the Board of Education for a grant for its medical departments. Opposition was at once raised on the ground that acceptance of State aid would lead to government interference, which would be against the best interests of the University, and that one faculty ought not to be allowed to commit the whole to a departure, save to lead to a rapid and wide extension of the principle. The Board of Education had declared they would not assume or claim power to discuss the character of the scientific teaching or interfere in any way with the internal affairs of the University. But the opponents replied that the present Board could not bind their successors. The supporters of the proposal assert that the fear of governmental interference is but a vague presumption; that the University was not asked to apply for an ordinary grant, but only for its share in a sum set aside specifically by parliament for the teaching of medicine and of engineering. It was accepted by Oxford for engineering—why not by Cambridge for medicine? The question aroused intense interest among Cambridge men and the dispute was fought to a close finish. So keen was the contest that at once there arose the question of whether the poll was final—which it seems to be—though some said the vote only sanctions the application, and it would be possible to oppose the conditions of acceptance. The victors retorted the conditions have been published and are most reasonable, the principle has been accepted by the University, and we shall obtain the grant as from October next. No doubt application will forthwith be made for the share in the grant, which is calculated at £4,600 a year; the school may, therefore, be congratulated.

The Harveian oration was delivered on Friday last by Mr. D'Arcy Power at the Harveian Society,

the President, M. Jackson Clarke, in the chair. "English Medicine and Surgery in the Reign of Edward III." was the subject chosen by Mr. Power, who said that the 14th century gave occupation to every branch of the healing art. Surgical work was called for on account of the hundred years' war. The Black Death gave work to practitioners of all sorts. At the end of the century, however, the War of the Roses completely changed the conditions. Prior to them there was a good prospect of those engaged in the work becoming a profession. John of Gaddesden was, perhaps, the best known medical man of the time and might be termed physician. John of Andern was the leading surgeon. In the Royal Library at Stockholm was a book by Andern dated 1412, a copy of which Mr. Welcome holds. Andern employed spells and charms so commonly used at that period. But the lecturer pointed out that he was much in advance of his time in surgery and invented new and original operations. Although Andern described his patients by their armorial bearings alone, Mr. Power had been able to identify one as the Mayor of Northampton in 1327. In those days a physician was always a churchman and usually held some preferment in the church. John of Gaunt had two friars as his physicians. Of operating surgeons there were two classes, one belonging to the Guild of Master Surgeons, a small body which required those who were in it to be of good repute. Those outside were under no obligations and naturally were less esteemed. At that time barbers were only barbers, but they acted as keepers of the city gates and a sort of officers of health, because they had facilities of discovering infectious diseases and preventing those suffering from coming in. There were also women practitioners at that time, as well as a number of groups engaged in distinct departments only—more or less subordinate. Dentists were well established. Apothecaries made and sold medicaments. Cuppers were a group to themselves. Couchers of cataract formed a specialty.

The lecturer gave a description of St. Bartholomew's Hospital in those early days and showed a number of lantern illustrations.

The Royal Soldiers' Daughters' Home has been invaded by diphtheria, and as there are about 160 girls, besides some 25 staff in the institution, no little uneasiness has been felt. There does not appear to have been any neglect and the committee have strictly followed the advice of the sanitary authorities of the district. The first case was on November 30, the second on December 4 last. Of course they were reported and inspection followed, the result being an intimation on the 12th that a number of improvements were desirable and a suggestion that their architect might advantageously confer with the Medical Health Officer, a course no doubt excellent, as a rule, but usually leading to costly alterations or rebuilding. The patients were conveyed to Asylums' Boards' Hospital as the law requires. Other cases appeared at intervals in January and February and at the instigation of the Medical Health Officer the throats of a number of the girls were freely swabbed to ascertain if possible who were the carriers. This was done early in February and a case occurred on each of the six following days after which there was freedom for more than a fortnight. Another case occurring, the Medical Health Officer's advice to have every person in the Home swabbed was carried out. The pathologist of University College Hospital was engaged to do this and report on the bacteriological results and agreed to do it personally, not by deputy. This was done, everybody in the building being included. No one after swabbing was allowed to mix with the unswabbed until all had been swabbed—about four hours' time. The bacteriological report revealed that above twenty persons were harboring the Klebs-Loeffler bacillus and forty were considered suspicious. These latter were isolated and treated with antitoxin—the others conveyed to the Asylums' Board's Hospital. Since then one case has occurred (on March 10). The committee propose, if practicable, to empty the building for a time long enough to carry out whatever renovations may be found necessary. The architect estimates that to do all the Medical Health Officer recommends will cost some £4,000. The expense of providing for the children during the period of renovations must be considerable and one feels inclined to inquire whether it might not be more economical to sell the building and remove permanently into the country.

Last night the matter was brought before the Hampstead Borough Council when a Councillor stated that arrangements were made for emptying the Home. The Medical Health Officer for Wandsworth, into whose district the girls are to be taken, has been informed and will cooperate in measures to prevent infection being carried.

The governors of the Mount Vernon Hospital for Consumption on Wednesday approved of the sale of the premises to the Medical Research Committee for the sum of £35,000, payable as to £11,000 in cash and the remainder in four annual instalments. The governors own another hospital at Norwood on which the committee will concentrate their future efforts—the architects having already prepared plans for its extension.

King Edward's Hospital Fund has received £269,644 as its share of the first distribution of the estate bequeathed by the late Sir Julius Werner.

The Fothergillian Gold Medal of the Medical Societies of London for 1914 has been awarded to Dr. Geo. Adami of Montreal University.

Sir W. J. Thomas's provision of £60,000 towards establishing a medical school in Wales is supplemented by an anonymous donor of £30,000 on condition that the treasury add to its present grant an amount which Sir W. Osler shall consider enough for an up-to-date school.

The Medical Health Officer for Hendon considers he has traced to a fountain pen three cases of scarlet fever in a family. The pen was destroyed and compensation paid. What of other pens?

Dr. George Ernest Herman, obstetric physician to the London Hospital (1876-1903), died on the 11th inst. at the age of 65. He qualified in 1870 and continuing work at the London Hospital took the M.B., London, in 1879. In due course he became a Fellow of both Royal colleges and held a number of appointments connected with obstetrics, of which he was recognized everywhere as a leading authority. Thus he was examiner on the subject at both the colleges as well as at the universities of London, Cambridge, Oxford, Durham, and Manchester (Victoria). The presidency of societies fell to his lot and the honorary Fellowships of foreign associations. His "First Lines of Midwifery" and "Students' Handbook of Gynecology" were textbooks in many schools, and as well known was his "Diseases of Women," while his "Difficult Labor" was regarded as a safe guide in any emergency.

Surgeon-General Sir A. M. Branfoot, C.I.E., who was president of the Medical Board of the India Office from 1904 to 1913, died on the 17th inst. He was a Guy's student, took the diplomas of the two Royal colleges, 1870-1, and graduated M.B. at the London University 1902, entering at once the Indian medical service, from which he retired in 1903, passing the following year, as stated above, to the presidency of the London Board. He had been made Companion of the Order of the Indian Empire in 1898, and was knighted in 1911. He served on the Council of the Lister Institute.

The deaths of two other retired medical officers of distinction have occurred: Surg.-Major Mark Robinson on the 13th, suddenly at Mentone; on the 17th inst. Fleet-Surgeon (R. N.) George Robertson, M.D., in his 74th year.

Dr. Francis Vacher, J.P., M.O.H., F.C.S., died on February 25 on a voyage undertaken for health, age 71. He was Medical Officer of Health at Birkenhead for nearly twenty years and held some other offices of the kind, had served as president of the Society of the Incorporated Officers, and of the Birkenhead Medical Society, and of its Literary and Scientific Society. He was a member of Société Francaise d'Hygiène, the Royal Institute of Public Health, and other associations connected with sanitation. He also occupied himself with various philanthropic efforts, both general and local, and is deeply lamented in Birkenhead.

## THE THEORY AND PRACTICE OF "CERTIFIED MILK."

To the Editor of the Medical Record:

Sir:—A prescription, unsuspectedly dangerous, becomes harmful in the ratio to the reliance placed upon it and its freedom of use. I quote from *Hoard's Dairyman* the following: "As evidence that the producer is willing to produce milk of quality as generally defined in terms of equipment and labor of production, Professor Harding stated that dairymen in New York City were prepared at the present time to produce two quarts of certified milk to every quart now used. One difficulty pointed out by Professor Harding was the fact that quality is not properly expressed in terms of practice at the present time. This is evident, for out of 28 or 30 bottles of certified milk in a show recently judged by Professor Harding, all but one bottle showed dirt at the bottom that was visible to the naked eye." In practice 90 per cent. of the dirt present in milk is found to be cow manure, and even healthy cows have a way of voiding tubercle bacilli with their feces. The certified milk requirements read " . . . strained through strainers made of a double layer of finely meshed cheese cloth or absorbent cotton thoroughly sterilized." From Professor Harding's statement either absorbent cotton or gauze, as a strainer, is not efficient in practice (and as the milk samples were entered in competition it was safe to assume that the milk was so strained), or the operators are negligent, for unless Professor Harding's vision was at fault the dirt was there present. And with mechanical milk cleansing means at hand, and largely and successfully used by other milk purveyors, why do the certified milk requirements still hold to the antediluvian straining methods, that seemingly, for some reason or other, don't strain. Certified milk carries with it an idea of "up-to-the-minute" sanitation which Professor Harding's findings seriously question.

Again, I quote from the U. S. Department of Agriculture Experimental Stations Report, which quotes from Dr. Rosenau as follows: "Milk drawn in a sterile way from normal cows may contain virulent streptococci and penumococci; hence, 'certified milk,' while surely less contaminated than ordinary milk, may contain pathogenic bacteria, and the advisability of pasteurization even in this case should be considered, especially during seasons when sore throat is common. Butter and milk may contain virulent streptococci."

Again, I quote from the certified milk requirements: "Certified milk and cream shall not be subjected to heat unless especially directed by the commission to meet emergencies." Remembering that there is such a thing in the dairy as the undetected tuberculous cow (the tuberculin test, though reliable, eminently so in practice, is not infallible), that a healthy cow will and frequently does void the tubercle bacilli in her feces, that foreign stable matter does get into the milk-pail despite all sanitary measures of prevention, that 90 per cent. of all foreign matter present in milk is cow manure, and that undetected and undetectable udder disorders may mean streptococci-laden milk, the infectious sore throat kind; then why in the face of all the above, if certified milk is to be banked upon as an absolutely reliable milk when all other milks fail, should not certified milk requirements demand that, to make this milk really, absolutely reliable, mechanical cleansing, clarification, be resorted to and the influence of the sediment that was removed from the milk mechanically, but yet present in a pathogenic germ sense, be nullified by pasteurization?

The antiquated fetish-like arguments against pasteurization, like floating corks, keep bobbing above the surface, but pasteurization has come to stay and its success in every-day practice, year after year, and in the cases of thousands upon thousands, hundreds of thousands, of infants whose lives have been saved by it, should quiet all hostile argument. The outcome of the Straus milk stations alone should be in itself convincing argument enough along practically utilitarian and eminently successful lines. To conclude, I exclaim, let the Milk Commission make the word "certified" mean really something along safety lines when applied to milk.

Charles Cristadoro.

1. The Treatment of Syphilitic Diseases of the Central Nervous System by Intravenous Injections of Salvarsan. L. H. Spooner.
2. Salvarsanized Serum ("Swift-Ellis Treatment") in Syphilitic Diseases of the Central Nervous System. J. B. Ayer.
3. Epicondylitis (Franke) or Tennis Elbow. W. P. Coues.

**1. The Treatment of Syphilitic Diseases of the Central Nervous System by Intravenous Injections of Salvarsan.**—L. H. Spooner concludes that it is possible to treat in a satisfactory manner syphilitic diseases of the central nervous system by intravenous injections of salvarsan in an ambulatory clinic. Small doses of the drug are necessary for this purpose, but such dosage yields results. With the exception of six cases placed subsequently on serum treatment and excluded from the author's paper, symptomatic improvement has resulted from thorough treatment in a high percentage of cases

of tabes and in all cases of syphilis of the central nervous system. No distinct improvement has resulted from the treatment of the few cases of general paresis under observation. Improvement in strength and gain in weight is the rule in those who receive benefit. The relief of lancinating pains in tabes and headache in cerebral syphilis is most striking. Biological and cytological changes (in blood and spinal fluid) indicate that there is an organic basis to this symptomatic improvement. It is regrettable that those observations were of necessity so limited. Improvement has been maintained over a long period of time—in many instances for from one to two years. The results of laboratory investigations when obtainable and the amelioration of symptoms correspond. Whereas the failures have been in old standing cases it is impossible to show any constant relationship between the degree of improvement and the duration of the nervous lesions. The most striking improvement follows the first or second injection. Treatment must, however, be persistent and prolonged and should be continued even if all symptoms and laboratory findings have long disappeared. Reactions are infrequent with small doses of the drug. Accidents are rare. Focal accentuations of symptoms (Herxheimer) are disagreeable but of short duration. These are often a hopeful sign. The most pronounced successes are in those who show evidence in blood or spinal fluid of intense syphilitic infection. The failures have occurred in those showing feeble reactions. Phthisis seems worthy of consideration as a contraindication. This treatment might well be advised in all cases of syphilitic disease of the central nervous system and abandoned for the serum treatment when conscientious effort in this simple and safe procedure has failed.

**2. Salvarsanized Serum ("Swift-Ellis Treatment") in Syphilitic Diseases of the Central Nervous System.**—J. B. Ayer draws the following conclusions from the use of salvarsanized serum, the procedure elaborated by Swift and Ellis: The method is safe. It is effective in many cases where other treatment has failed. It undoubtedly attacks syphilis from the etiological point of view, thus tending to cure the disease as well as relieve symptoms. Its greatest effect is in the group of cerebrospinal syphilis, in which a cure may confidently be looked for in some cases with persistent treatment; second, in tabes, in which arrest of disease process is often possible by this means; least effective in general paresis, when well developed, though here if taken in the preparetic stage encouraging results may be obtained. With the originators of the method the authors agree that persistence in its use is the keynote to success in the salvarsanized serum; consequently an estimate from the injection of one or two doses is a judgment more of the "reaction," which in some cases is severe, than of the therapeutic effect of the serum. With the technique of administration and necessary control examinations as laborious as at present the authors do not expect to see this form of treatment in general use, but believe it should be employed by those especially trained when other treatment fails in whole or in part, or in cases where haste is required in order to save vital tissue.

**3. Epicondylitis (Franke) or Tennis Elbow.**—W. P. Coues points out that there might perfectly well be two lesions causing the symptom complex known as tennis elbow, or epicondylitis. First, a partial tearing of some of the muscular attachments from the external epicondyle, giving rise to the separation of bony spicules, with the possibility of a periostitis from such tearing, which need not necessarily be marked enough to show in a radiograph. Second, injury to the radiohumeral joint capsule from antagonistic muscular contraction of the supinator brevis and supinator longus, as believed by Preiser. It does not seem as if Preiser's theory of predisposition to arthritis deformans of the radial head could be accepted in all cases.

**1. Treatment of Chronic Nephritis.**—J. Tyson states that the indications are first to protect the system against toxins which tend to accumulate in the blood because of deficient elimination by the damaged kidney; second, to protect against complications and certain grave symptoms and their consequences; third, to restore the normal structure of the diseased organs. The first indication is met by cutting out protein foods, whence for the most part arise the toxins referred to, and, second, by stimulating the function of organs other than the kidneys whose office it is to supplement the renal excretion. Quite as important as the quality of food is the quantity. Overeating is often the cause of nephritis; especially therefore should it be avoided by the nephritic. Having cut down protein foods and substituted others the next step is to stimulate the excretion of the toxic products of deranged protein metabolism. The functions of the kidneys are stimulated by the saline diuretics, of which potassium citrate is the type, and by the alterative diuretics as iodine and calomel. The skin is also an efficient agent in eliminating toxins. It is availed of most effectually by the hot pack, the hot-air bath, hot vapor bath, or electric light bath. There can be no doubt that the kidney is subject to structural repair. All that promotes natural and normal function and maintains normal circulation, tends to promote healing. The complications of chronic nephritis are numerous, but only a few demand detailed consideration. They include bronchitis, edema of the lungs, pneumonia, pericarditis, more rarely endocarditis, pleurisy, and effusion into the serous sacs. Among symptoms requiring special or modified treatment are uremia and edema, general and local. A brisk purge, a sweat, or a bloodletting may avert the threatening convulsion and coma of anemia. The presence of coma or convulsions militates against the usual modes of giving medicine. A couple of drops of croton oil mixed with a teaspoonful of plain oil may be carried to the back of the tongue, or one-sixth grain of elaterium or one-twelfth grain elaterin dissolved in a small quantity of water. Chloroform may be inhaled to control the convulsions. After the purgative has had its effect an enema of chloral in solution, as much as a dram of the drug in four ounces of water, may be given to supplement the effect of ether and to continue it. Simultaneously, or in close association with these measures, is the sweating which may have been used in the initial stage of treatment. The best method of securing sweating at this stage is by the hot pack or vapor bath. The fluid extract of jaborandi or pilocarpine hydrochloride may be used to facilitate the action of heat, small doses such as a quarter of a grain of pilocarpine being sufficient when combined with the heat; while large doses, though more active, are apt to produce edema of the lungs. The operative treatment of chronic nephritis, Edebohl's operation, is not resorted to as often as it should be.

**2. Conservation of the Functions of the Ear, Nose, and Throat.**—W. S. Bryant refers to the importance of

the integrity of the ear, nose, and throat. The danger from soot, dust, and poisonous gases in every occupation where they occur should be recognized by law and should be minimized by law. When the public is sufficiently educated to appreciate the loss through these remediable hardships it will not be slow in demanding salutary legislation, and in punishing the offenders by legal penalty and public opprobrium. The special means of protection in every instance are obvious. We should view this subject from the viewpoint of the people most affected. Public sentiment should be aroused by an exposition of the dangers and losses from remediable causes, and protective legislation providing general regulations should follow. Public sentiment should be aroused through an appreciation of the value of the functions of the ear, nose, and throat to an active campaign to preserve these functions for the coming generation. Public sentiment should also be moulded to revere as sacred the respect due to the promptings of their sense organs, and to appreciate the value of the warnings and the great danger which these sense organs point out. It should be compulsory that children have the necessary attention to their ears, noses, and throats. The importance of keeping dust down is shown by London, which, largely on account of its dust-free foggy air, is the great health city. We must now choose the means to approach the end in view without dangerous speed, but with the evidence of advance. Legislation should compel all large users of coal to destroy or mitigate all acid fumes and volatile, poisonous elements, and consume all smoke, thus improving the air for breathing. The dust problem does not require legislation as the problem of effluvia does. It can be regulated by city ordinances and by public opinion, which should demand a city ordinance providing for sprinkling oil or a hydroscopic fluid in the streets to lay the dust at all times of the year. Vacuum cleaners, Dr. Bryant maintains, should be used in all public buildings, places of business, manufactories, hotels, and apartments.

8. **The Dose of Hexamethylenamine.**—F. D. Austin concludes that the Ramini-Burnam and phloroglucin tests are very simple, and when used give the physician the earliest method of determining the dose of hexamethylenamine in any given case. It is the duty of every physician who gives the drug to make the test, for without it he cannot possibly know the amount of free formaldehyde he is getting. These tests are of great value in determining the formaldehyde value of the many urotropin compounds. The allied compounds fail to give greater antiseptic values than the pure hexamethylenamine. The conclusion of different investigators in regard to the antiseptic value of hexamethylenamine in the alkaline fluids of the body, is that it is according to laboratory findings absolutely valueless, that it occurs in too weak a dilution, if at all, in the free state. The author has no explanation to offer for the often reported clinical and bacteriological improvements of the secretions, other than the urine, for the author has not tested them as he has the urine. The conversion of hexamethylenamine into formaldehyde is a simple process which will readily occur in an acid medium, but not in an alkaline one. The amount of free formaldehyde excreted is influenced by the size of the dose, by the frequency of its administration, by the degree of acidity in the body fluids, and by the body heat. The low acidity of the urine can be greatly overcome by giving certain acid producing drugs. The ordinary dose of five to seven and a half grains of hexamethylenamine three times daily will fail to give free formaldehyde in an amount sufficient to be of any antiseptic value.

1. **Histogenesis of Multiple Basocellular Carcinoma.**—R. L. Sutton concludes that the theories of Thiersch and of Cohnheim are not tenable in all cases of cancer. In basocellular carcinoma the tumors spring directly from the basal layer of the rete, and are independent of proliferative changes in the corium. It is improbable that either the blood-vessels or substances within the blood-vessels exert any influences on the course or character of the lesions. An important if not absolutely essential, factor in the etiology of both basocellular and prickle-cell cancer is a peculiar quality of the skin, a quality which may be acquired but is frequently congenital and occasionally inherited, and which is characterized by harshness and dryness, with more or less evidence of long-standing dry seborrhea. Judging from the regions commonly involved, exposure to sunlight and to atmospheric changes also plays an important part in the preparatory degenerative process. The long-continued action of the Roentgen rays may give rise to cutaneous changes which predispose to cancerous involvement, but this predisposition is limited to the area exposed, and would not account for an increased susceptibility of the skin on other parts of the body.

3. **Formaldehyde.**—H. McGuigan concludes that formaldehyde is rapidly absorbed from all parts of the gastrointestinal tract and lungs, and may be excreted again by them. It is rapidly oxidized in the body to formic acid and carbonates. There is also a small amount of a dialyzable compound formed in the blood, which is most probably hexamethylenamine, since the latter is found in the urine. Small amounts of formaldehyde may pass through the body without causing apparent inflammation, while larger amounts always cause some. Recovery from severe inflammatory reactions may be rapid and apparently complete. Formaldehyde depresses the heart by direct action. Its action on respiration is transient and apparently the result of irritation, though the quick oxidation would account for some of the increase. Formaldehyde causes a stimulation of the intestinal movements, which, in the case of large doses, are extreme. The antiseptic action of formaldehyde is apparently due to fatigue. exhaustion, and a final firm combination with the drug. There is nothing to indicate that the drug has a field of usefulness in medicine other than for local use.

5. **Hemolysis Due to Intravenous Injection of Distilled Water.**—E. B. Krumbhaar has found that the rapid intravenous injection of distilled water, in amounts equal to from 2 to 3 per cent. of the bodyweight or more, will cause in the dog transient hemoglobinuria and albuminuria. Lengthening the duration of injection time from five to forty-five minutes is without noticeable effect, though a much slower injection might give different results. Hemoglobin stained urine usually appears in the bladder catheter in from twenty-five to thirty minutes after the beginning of the injection. The hemoglobinuria lasts approximately from four to sixteen hours, depending on the severity of hemolysis. Much smaller amounts (as low as from 0.4 to 0.6 per cent.) are sufficient to cause a noticeable hemoglobinemia without hemoglobinuria. Hemoglobinemia appears within from two to four minutes after the beginning of the injection and may last twenty-four hours. In doses that just fail to cause hemoglobinuria, albumin and bile may appear in the urine the next day. No noticeable anemia is caused, but there is a temporary decrease in the minimal resistance of the red blood cells.

7. **Blood Transfusion in Diabetes Mellitus.**—B. O. Raulston and R. T. Woodyatt state that the transfusion of 500 c.c. of peripheral venous blood from a healthy male donor into the peripheral veins of a brother suffering from severe diabetes mellitus had a decided effect on the metabolism of the latter, as evidenced by a marked rise in the output of sugar, ammonium, and acetone bodies, and an increase of the glucose to nitrogen ratio. In severe diabetes mellitus blood transfusion is definitely contraindicated.

12. **A Clinical Study of Asthma.**—B. C. Davies rejects the older classifications of asthma and even the more recent one of intracardiac and bronchial asthma, and considers it only as a reflex acting on the innervation of the circular muscular fibers from irritation from other parts of the body causing hyperemia of the bronchial mucosa and spasm of the muscular fibers and of the diaphragm. The author quotes in support of these views cases in which the asthma was due to gastrointestinal disorders, adenoids and nasal troubles, genitourinary irritation, etc., and was relieved or cured by treatment of the causal conditions. He suggests, reasoning from his own experience, that asthma be no longer considered a disease entity but as a reflex symptom. The examination in these cases should be complete and exact. The treatment very often lies in preventing the attacks; hence it is in the hands of the patients to a large extent, and they should receive full instruction as to its cause and prevention.

13. **Whooping-Cough.**—A. Friedlander and E. A. Wagner find that the complement-deviation test is of the greatest value in the diagnosis of whooping-cough, though Bordet himself, who described the bacillus, concluded that complement-fixation was not an early sign. Their technique for the test is described as follows: "A small amount of blood was taken from the patient's ear, finger, or toe in small test tubes or in Wright capillary tubes. This was kept at room temperature or placed in the incubator until coagulation had taken place. Serum was then separated more completely from the clot in the centrifuge. So far in the authors' tests the fresh active serum has been used. Two drops of the serum were used in each test. Hemolytic system: The Noguchi system was used because of its extreme delicacy and because of the small amounts of material, especially serum, required. Antigen: This is the most important factor in the test. The Bordet-Gengou bacillus was obtained in pure culture. Subcultures were made on Bordet's medium, ascitic fluid agar, and broth serum. The antigen was made from seventy-two hour growths in ascitic fluid agar in the following manner: The colonies which are very tenacious were washed off the agar with sterile salt water. An emulsion was made, and the bacteria were again washed in salt water. From this a standard suspension was made and 0.1 and 0.2 c.c. of this were used in the test. Throughout the tests live bacteria were used. Controls: In each test known normal and known positive tests were used. In each series of tests the hemolytic system was tried out in the usual manner, using a water bath at 37° C. incubation. After primary incubation for half an hour the amount of amboceptor indicated by the preliminary test was added to the final test tubes, and the tubes were again incubated in the water bath. Final readings were taken within the following hour." In each case independent readings were taken by the two authors without the previous knowledge of the clinical history and the tabulated results are given showing their uniformity of positive reactions in cases of pertussis as compared with other conditions. The authors call special attention to the need of fresh antigen in the test.

15. **Pseudopancreatic Cysts.**—F. A. Besley criticizes the term "pseudopancreatic cysts" and gives an account of four cases. The condition is essentially a collection of fluid in the lesser peritoneal cavity and not a true cyst, and only resembles a pancreatic cyst in that the fluid sometimes contains the pancreatic ferments. Three of the four patients whose cases were described were children that had been run over by wagons. The other was an adult who had received his injury in a railroad wreck. Each case gave a history of severe abdominal pain with nausea and vomiting immediately following the accident. There were fever, tenderness, and rigidity, which lasted until the tumor was recognized. The author thinks the tumor can be made out in eight to ten days if carefully searched for and its appearance after an injury, protruding to the left above the umbilicus, together with the other symptoms mentioned, rendered the diagnosis of fluid in the lesser peritoneal sac, most probable. All the cases were treated by incision and drainage.

5. Etiology of Endemic Cretinism, Congenital Goiter, and Congenital Parathyroid Disease, Abstract of Experimental Researches. R. McCarrison.
6. The Suppression of Reverse Current in *X*-Ray Coils. R. Morton.

1. **The Biology of Tumors.**—C. Mansell Moullin believes that tumors, no matter what their clinical character may be, are caused by the sudden escape from control of the innate power of asexual reproduction present in some measure in all tissues as part of their life. So long as development is advancing, growth and reproduction are under control. But development depends upon special work, and work in its turn depends upon the special chemical reactions which have been evolved. If these reactions are interfered with, whether by the addition of strange elements or the failure to supply necessary ones, work comes to an end; development stops with it; and the power of growth and reproduction, or that measure of it which the tissues possess at the moment, is set free without limit, except in so far as supplies are concerned, and without control. In the illustrations which the author gives the interfer-

ence with the nutrition and the chemical reactions of the tissues have been caused by the slow continuous working of substances introduced into the body from without. Some have entered through the digestive tract, others through the lungs, and others again through the skin. It does not seem to the author unwarantable to assume that a similar interference can be caused by substances produced in the body itself, more especially as age advances. It need not necessarily be from the place where the tumor grows. It may be at some distant spot from which the substance is carried by the blood stream, as it is, for example, in the case of arsenic. It may be some minute difference in one of the constituent elements of which one is as yet incapable of judging, or there may be an additional one introduced, or some essential one may fail at the moment it is wanted. This is the direction in which one is to look for the next great advance in the biology of tumors, and this is the direction in which investigation should be made.

4. Arteriosclerosis.—L. Williams states that if one would understand the real causes of arterial degeneration one must look deeper than the banal surface causes, such as gout and syphilis, which are not always operative, to the limestone formation which lies beneath. Here one comes upon the powers of resistance of the individual, which rest upon his metabolic efficiency. This in its turn is supported by the vigor and harmony of his ductless glands. When the vigor and harmony of these glands are impaired by circumstances which may be congenital or acquired, the metabolic efficiency deteriorates and the powers of resistance decline. Toxins now succeed where before they were defeated and degenerative processes become operative. In the degenerative processes which attack the vascular system the fibrosis and the calcareous deposit are originally conservative measures which proceed to dangerous excess only because of the want of control of the endocrinous glandular system in general, and of its master gland, the thyroid in particular. Thus in the presence of vascular degeneration one is powerless. When one is appealed to early enough, one may do something to defer its arrival, and the degree of that something will depend upon one's working knowledge of the physiology and clinical behavior of the ductless glands. If one can learn to stimulate the efficiency and promote the harmony of these potent metabolizers one may do much. Without such knowledge one is impotent. But sooner or later, by one means or another, whether by calcium or fibrosis, or what not, the end must come. Even though man should live by bread alone, eschew wine, laughter, and song, he cannot escape.

5. Etiology of Endemic Cretinism, Congenital Goiter, and Congenital Parathyroid Disease.—R. McCarrison presents the following conclusions: Of the offspring of goitrous parents, a small percentage are born cretins; approximately 63 per cent. are born with congenital goiter; 32 per cent. are born with congenital parathyroid disease; and 33 per cent. are born with normal thyroid and parathyroid glands. Cretinism and congenital goiter are due to the action of toxic substances derived from the intestines of the goitrous mother on the fetal thyoparathyroid mechanism. Cretinism represents the maximum, and comparatively rare, effect of these toxins; congenital goiter their minimum and comparatively common effect. Between these extremes all degrees of thyroid involvement may occur with or without associated swelling of the gland. Congenital parathyroid disease is due to the action on the fetal gland of the toxic products of the organism, present in the intestine of the goitrous mother, which are capable of growth under anerobic conditions.

4. Cancer, Public Authorities, and the Public. C. P. Childe
5. Experiences of the National Health Insurance Act. E. F. Pratt.
6. The Milroy Lectures on the Hygienic Aspect of the Coal-mining Industry in the United Kingdom. F. Shufflebotham.

1. The Art of Prescribing.—A. P. Luff states that there is a tendency nowadays to adopt a sceptical attitude as to the utility of drugs and to regard them as mere placebos. It is an attitude which the author has specially observed in those who have neglected to acquire any thorough knowledge of the use of drugs and of their methods of correct administration. One should not be over-influenced by the brilliant work that has been done, and is still being done, in the inoculation departments of various hospitals. While pleading for greater attention to the art of prescribing, the author does not question the usefulness of inoculation treatment, since he is fairly constantly employing it in his own department of work, and is therefore well acquainted with its utility in certain diseases. But it is a method of treatment which has its limitations; for the great bulk of the ailments one is called upon to treat are not cases for inoculation treatment, but require the prescription of drugs. In the author's opinion, the main reasons for the present decadence in the art of prescribing are the altogether inadequate attention given to the teaching of the subject by the majority of the members of the staffs of the various teaching hospitals, and the scanty test applied by so many of the examining bodies as to the possession of a knowledge of rational prescribing on the part of candidates presenting themselves for the final examinations. The want of attention to the teaching of the subject in the large hospitals is certainly in some measure due to the over-pressure of work consequent on the number of patients that have to be seen and treated in a given time—an over-pressure which necessitates, to some extent, the ordering of medicines already prepared according to some formulæ in the hospital pharmacopeia. The prescribing of these ready-made medicines undoubtedly saves the time of the physician or surgeon and of the dispenser; but, unfortunately, the outcome of the custom of ordering ready-made mixtures, etc., is that the students soon fall into the habit and carry it with them into private practice. Consequently they have no opportunity of acquiring confidence in their own powers to write a useful prescription. It has been stated that the hospital practice of ordering mixtures, pills, etc., by the titles under which they appear in the hospital pharmacopeia is not detrimental to the acquisition of a knowledge of a correct prescribing, since the student can always refer to the pharmacopeia for information as to the composition and strength of the medicine ordered. The author, however, strongly maintains that the information so obtained is in no sense comparable to the educational advantage of hearing the dictation of a prescription in full. There is no better method of acquiring a knowledge of correct dosage, and of the avoidance of incompatible ingredients, than by hearing the physician or surgeon dictate his prescription, comment on the dosage of the ingredients, and give his reasons for the employment of such ingredients. On the other hand, if it is left to the student to look up the composition of a medicine from the hospital pharmacopeia, he is apt to forget to do so, and certainly he could never in that way either acquire a title of the knowledge or retain the information so well in his memory as by hearing the dictation of a prescription in full.

*March* 9, 1914.

**Pathology of Syphilis and Curative Action of Salvarsan.**—Von Zeissl, like some of his contemporaries, reviews the history of the treatment of syphilis, in order to make a full comparison between salvarsan and the older remedies. The fact is well known, although often forgotten, that intensive treatment with mercury extends back at least to the first reports about the new disease, if not beyond that period—a document used at times for teaching the relative antiquity of the disease. Schellig, the oldest writer on syphilis, speaks of sweating and mercury as two very important remedies. Hensler, the historian, states that mercurial treatment must have reached to some technical development, else it would not have been applied intensively to an unknown disease. For years we have such favorable reports as to mercury that the author compares it with salvarsan. Meanwhile, an opposition movement had developed, as is also the case to-day with the new drug. This was offset by a more rational use of mercury. Up to 1600 even inunctions were proscribed, as, likewise, fumigations. During the next century the war on mercury increased in severity as a result of new forms of abuse, until its indication, as far as the lay mind was concerned, became extinct. Professional condemnation also existed, and continued into the nineteenth century. Then the fabric of antimercurialism was reduced to absurdity when Hermann, a Viennese syphilographer of good standing, actually taught that mercury was the cause of so-called constitutional syphilis. Not until the pathology and natural history of untreated syphilis were known was it entirely possible to discriminate between hydrargyrism and syphilis. The contagiousness of gummata in rare instances showed a unity of syphilis in point of time. After the discovery of the spirochete our knowledge of the disease has increased notably. In regard to the sudden appearance of nerve lesions after salvarsan, research into older works reveals similar conditions in untreated or mercury treated cases. Thus, Mauriac, in 1878, reports cases with evident encephalitis developing very soon after the chancre. Cases of sudden deafness, blindness, etc., are recorded in abundance in the eighteenth century.

**Shellac Concrements in the Stomach and Duodenum.**—Hallas gives a brief monographic account of this rare find, including personal experience. Only a few isolated cases are upon record, the first in 1865, and apparently not over half a dozen authors have reported cases, Hallas, having seen two, which unusual experience caused him to look up the entire subject. In the various cases the concrements were accidentally found. The rarity of the find must not be judged by reported cases, for the pathologists in various countries speak of finding them on rare occasions. A diagnosis *in vivo* is apparently impossible, but a history of varnish drinking, or the mere occupation of the patient, could suggest the presence of such concrements.

**Does Precocious Puberty Imply Mental Precocity?**—Münzer cites a few cases of precocious sexual development in boys and girls. A female, fully developed sexually at the age of six years, was carefully followed up by experts with regard to her mental development. They learned that while physical growth went ahead with unusual rapidity, the psyche did not keep pace with the soma in this respect, and was, in fact, far behind it. In a similar case, in a ten-year-old girl, one saw the face of a woman of twenty-two associated with a childish disposition. It is true that the opposite relationship is seen. For example, a girl of five, sexually precocious, was intellectually mature. This patient had a tumor on the pineal gland. In a few other cases there has been harmony between sexual and mental precocity, but as a rule dysharmony is present.

### Deutsche medizinische Wochenschrift.

*March* 12, 1914.

**v. Behring-Ehrlich Jubilee Number.**—This journal, in common with the *Berliner klinische Wochenschrift*, celebrates the sixtieth anniversary of the birth of these two eminent scientists. Römer contributes a joint appreciation of the latter and their work. Otto writes at length of the native antitoxin in the blood of healthy subjects, convalescents and carriers, and Joseph discusses anaphylaxis and its prevention. Ruppel covers the subject of the changes in the specific treatment of diphtheria, and Boehncke gives the practical results of serum control. These with several minor papers complete the von Behring contingent. The Ehrlich contributions deal naturally with chemotherapy and immunotherapy. Von Wassermann writes of the action of radioactive substances on mouse cancer, and Apolant and Bierbaum on the successful inoculation of the latter into rabbits. Anthrax immunity is discussed by Wernicke, and tuberculosis immunity by Römer and Siebert respectively. An important contribution to bacterial disinfection and chemotherapy is made by Ehrlich's old collaborator Morgenroth. Finally Roux and Metchnikoff write in honor of von Behring. To descend to details among so many valuable articles will almost seem invidious, so that certain statements are selected at random. Otto says of von Behring's serum that new researches only support the original contentions. The nurses and attendants in diphtheria wards are those who are most exposed to contagion; in fact are never free from exposure. A large part of the antitoxin in daily use is therefore bespoken by adults. Carriers, including permanent excretors of bacilli, show a high blood content of antitoxin, convalescents are much lower. As a rule a single diphtheritic infection seldom confers a high degree of immunity; to secure the latter several attacks are probably required. Healthy carriers sometimes go through masked or latent attacks of the disease, as shown by the increased blood content of antitoxin. Joseph states in regard to the prevention of anaphylaxis that the fear expressed in this connection is without foundation and that in any case we have a complete set of preventives for this state, including the production of antianaphylaxis and the application of diphtheria ox serum. In case of a personal history of antitoxin injection or suspicion of the same, we may resort to the Neufeld-Besredka or Friedberger-Mita methods of producing antianaphylaxis. In this condition the sensibilized organism is refractory toward any amount, however small, of antitoxin. In case of an initial injection, notably for prophylactic purposes, the diphtheria ox serum should be used, so that if high-value horse sera have to be given afterward anaphylaxis will be strongly combated. Conversely should a patient have been sensibilized by horse antitoxin the ox serum may be used for second injections. Every effort should be made to antagonize anaphylaxis, for this is the turning point in the general attitude toward serotherapy as a general method of treatment. A point naturally not touched upon in these jubilee papers is the somewhat hostile attitude of Ehrlich toward serotherapy in general, while admitting that several antitoxins have been phenomenally successful. In other words Ehrlich believes that antitoxin therapy has reached its zenith and that chemotherapy must take its place in the future. Von Behring is perhaps of the same opinion, as all his efforts in this field are in the direction of improving his antitoxin.

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINER.

BY THE INSURANCE EDITOR.

### THE IMPORTANCE OF BLOOD PRESSURE TO LIFE INSURANCE.

THE following suggestions were offered at the twenty-fourth meeting of the Association of Life Insurance Medical Directors of America, by a committee appointed to consider the question of blood pressure in reference to life insurance.

1. The taking of the blood pressure should not be required unless the applicants are forty years of age or over and applying for $5,000 or over. The opinion was unanimous that no advantage will be gained by requiring the blood pressure at ages under forty, but several favored it without regard to the amount involved if the age is forty or over. As most applications for $5,000 or over come from towns of a size where examiners are specially trained to take blood pressure, and as it is the larger insurers who are especially exposed to the social and business stress favoring high blood pressure, it was agreed that little will be gained by requiring the test with small applications, since the difficulty in securing reliable records will be greater in these cases. As age and amounts increase, the temptation to withhold and conceal information becomes correspondingly greater, and as these are the cases especially exposed to diseases in which high blood pressure plays an important rôle, the need of the test becomes more urgent.

2. While the clinical value of diastolic pressure was acknowledged, it was considered of slight value in apparently healthy individuals and difficult to obtain correctly except at the hands of experts.

3. Kind of instrument. All the present sphygmomanometers are more or less imperfect and not especially adapted to this work. The name of the instrument used and the width of the cuff should be reported.

4. At least two readings should be made at each examination. Some thought there should be five.

5. Position of the applicant. The applicant should sit with the arm on a table so that the muscles might be quite relaxed.

6. The apparatus should be applied after the completion of the applicant's statements and before the physical examination, and again after the examination is completed. At least two or three readings should be made at each of the tests and the average recorded as the actual pressure.

7. An average of 150 mm. on two or three readings calls for a repetition of the test on several days and at different hours of the day.

8. It was agreed that a continued pressure of 150 mm. probably signifies some pathological trouble.

9. A previous history of albumin alone was not considered serious enough to demand the test. The test should, however, be called for in the following cases:

(a) A history of albumin and casts.

(b) A previous record of organic or functional heart trouble.

(c) A syphilitic history.

(d) Two or more apoplexies in the immediate family.

The writer agrees with the suggestions offered by the committee as a whole, but believes they would be improved by the following modifications:

1. Width of the cuff band. The necessity of the wide cuff has become so generally recognized that the narrow bands have disappeared entirely from the market; consequently, any requirement in regard to it is superfluous.

2. The impracticability of a demand for the diastolic pressure should be emphasized, as, aside from its lack of importance to life insurance interests, as far as is known, the results are unsatisfactory and practically valueless unless taken by the auscultatory method.

3. After long experience in testing for blood pressure the writer is convinced that the pressure should be read as soon as possible after the pulse has been obliterated. The point to be emphasized is that the first steps should be taken so carefully and with the mind of the operator so concentrated on his work that a second reading will not be necessary. The first reading records the correct pressure. Subsequent changes occurring during the same test, and these do occur rather frequently, consist of a fall due to the continued constriction of the arm, or a rise due to a state of increasing excitement. The change may begin as soon as a minute after the obliteration of the pulse and extend to 5 to 10 mm. Nothing is gained by prolonging the test so as to take two to five readings. If the observer is not satisfied with the first reading, he should remove the cuff and reapply it later when the subject is free from excitement.

4. While all portable sphygmomanometers are faulty, those made by good makers, mercurial or aneroid, will give accurate readings if checked up with large standard instruments at regular intervals and properly cared for. The mercury should be occasionally renewed as it is very susceptible to the action of oxygen. Even in the closed instrument the sulphur from the bag leads to the formation of mercury sulphide. A well made aneroid manometer compared regularly with a standard instrument is not excelled by any form introduced so far.

In discussing the report of the committee, Dr. J. W. Fisher, said that he had determined the minimum limit for rejection in the younger ages by adding 15 mms. to the average pressure for the age. Dr. Van Wagenen presented the following table showing the average systolic blood pressure by his company in accepted risks at ages 14-70:

| Ages | Number | Low Pressure | High Pressure | Average Blood Pressure |
|---|---|---|---|---|
| Under 15 | 1 | 115 | 115. | 115. |
| 15-20 | 95 | 104. | 145. | 121.18 |
| 21-25 | 307 | 90. | 148. | 121.79 |
| 26-30 | 300 | 100. | 150. | 124.64 |
| 31-35 | 325 | 90. | 155. | 124.77 |
| 36-40 | 588 | 95. | 158. | 126.62 |
| 41-45 | 1342 | 90. | 158. | 128.03 |
| 46-50 | 745 | 104. | 156. | 129.37 |
| 51-55 | 447 | 100. | 155. | 131.61 |
| 56-60 | 176 | 108. | 158. | 135.74 |
| 61-65 | 57 | 112. | 156. | 133.47 |
| 66-70 | 17 | 118. | 150. | 136.88 |
| Total | 4400 | 102.17 | 150.33 | 127.79 |

The averages in this table agree closely with those found in general experience. It would seem that the suggestion for the addition of 15 mm. to the average pressure of each age for determining the minimum limit of high pressure for that age can not apply unless there is some other serious impairment. For instance, it will be found in general practice that applicants at age 26-30 with no more against them than a blood pressure of 139 mm. will not have the slightest difficulty in securing insurance on their lives at ordinary rates.

# Book Reviews.

ORGANIC CHEMISTRY FOR STUDENTS OF MEDICINE. By JAMES WALKER, LL.D., F.R.S.; Professor of Chemistry, University of Edinburgh. Price $2.50 net. London: Gurney & Jackson; Edinburgh: Oliver & Boyd; New York: D. Van Nostrand Co., 1913.

THE aim of the author of this book is most praiseworthy. Appreciating the fact that the medical student has but little time to devote to chemistry, he selects only such chemical processes and substances as are of medical interest. The result is, of course, a much smaller book than the student has been accustomed to; but we doubt if it is entirely satisfactory. One of the difficulties experienced by the beginner in organic chemistry is to appreciate the meaning and significance of the terms used; the present volume is weak in this direction. Again, general principles are of more value to the medical student than isolated examples. The author's definition of an *asymmetric carbon atom* is rather vague; a *satisfied hydrocarbon* and a *saturated hydrocarbon* are not synonymous terms. The medical student should have some knowledge of all the branches of organic chemistry; this knowledge is requisite for an adequate undertaking of physiology, pharmacology, pathology, and hygiene. In the present work, however there is very little physiological chemistry. As an introduction to some work on biochemistry this book, with the limitations above noted, will serve a useful purpose.

THE AMERICAN ILLUSTRATED MEDICAL DICTIONARY. A new and complete dictionary of the terms used in medicine, surgery, dentistry, pharmacy, chemistry, nursing, veterinary science, biology, medical biography, etc., with the pronunciation, derivation, and definition, including much collateral information of an encyclopedic character, by W. A. NEWMAN DORLAND, A.M., M.D., Member of the Committee of Nomenclature and Classification of Diseases, of the American Medical Association; Professor of Obstetrics, Loyola University, Chicago; Fellow of American Academy of Medicine, together with new and elaborate tables of arteries, muscles, nerves, veins, etc.; of bacilli, bacteria, diplococci, micrococci, streptococci, ptomaines and leukomains, weights and measures, eponymic tables of diseases, operations, signs and symptoms, stains, tests, methods of treatment, etc. Seventh Edition, revised and enlarged. Price $4.50. Philadelphia and London: W. B. Saunders Company, 1913.

THE sixth edition of Dorland's Dictionary appeared in 1911, and according to the statement of the publishers over 5,000 new words have been added to this seventh edition. We trust that many of these are words that were omitted from the former edition, for it would be a matter of concern if so many new terms had actually appeared in the language of medicine in the course of two years. At this rate an up-to-date medical dictionary in 1924 will be as large as Webster's Unabridged or the Standard of this year of grace. The general features of the sixth edition have been retained in this, with the addition of some more copied from other dictionaries. The volume is of convenient size, not too heavy, and bound neatly in flexible covers.

DIAGNOSIS OF THE MALIGNANT TUMORS OF THE ABDOMINAL VISCERA. By Prof. RUDOLPH SCHMIDT, Professor of Medicine in the University of Innsbruck. Authorized English Version. By JOSEPH BURKE, Sc.D., M.D. Price $4.00. New York: Rebman Company, 1913.

THE author's long associations with Professor Neusser at the Vienna General Hospital and its unsurpassed clinical facilities have lent an air of undoubted authority to this excellent work, which has been ably translated by an American surgeon. The cases which form the basis of the book have been very carefully studied and in most instances confirmation of the diagnosis was possible at operation or autopsy. For this reason a large number of case histories are introduced in the concluding portion of the book. From a study of these it is evident that early diagnosis of malignant growths is usually omitted, from inexperience of the medical adviser first consulted—a fault evidently as prevalent in certain European countries as with us. The author therefore lays stress on the early symptoms, particularly of gastric, intestinal, and renal neoplasms and discusses very thoroughly the subjective phenomena which are so frequently the forerunners of the objective findings, but unfortunately often passed over by the physician as of little consequence. Prof. Schmidt calls them very pointedly "factors of suspicion." In the introductory chapter on physical examination attention is called to the value of palpation as compared with percussion and auscultation. He likewise comments on the advisability of restricting radiological examination to its proper limits, without desiring, however, to invalidate the importance of this procedure. In classifying according to merit the diagnostic measures that will aid in the determination of gastric cancer, for example, *x*-ray examination, according to Prof. Schmidt, should be placed at the bottom of the list, the clinical methods coming first. Concerning the presence of bacterial and other organisms as diagnostic factors, Schmidt believes that the finding of lactic acid bacilli in the stomach and feces cannot be regarded as specific and advanced cases may occasionally go on without this finding. The author claims that specific symptoms belong only to a certain definite disease process. They are among the greatest of all rarities and in the entire symptomology of malignant neoplasms there is no specific symptom. For this reason there ought not to be any strife in regard to specificity and non-specificity, but rather there should be an agreement as to what place a certain symptom occupies in the list of diagnostic values. The etiology of malignant tumors is discussed with interesting and valuable suggestions regarding history taking. Attention is called to two points worthy of note in forming an opinion as to the genesis of malignant tumors, first, that malignancy in many cases is superimposed on a benign tumor, therefore it will hardly do to presume that there are totally different kinds of origin for benign and malignant new-growths. Hence the study of tumor formations with reference to the etiology should really begin with the benign formations which frequently are the first steps of the malignant one. Second, the probability of a tumor theory must rest on the hypothesis that not only does it not apply to any epithelial growths, but also will be able to explain the malignant connective tissue growths, the more so as even here transitions seem to occur. Schmidt believes that prophylaxis in malignancy is of importance and includes both local and general hygiene. The local measures consist largely of the avoidance of irritants especially in individuals who have had gastric ulcer or other chronic inflammatory lesions in the intestinal canal. Nutritional excesses, according to the author, undoubtedly become predisposing causes in many individuals. General hygienic measures are also of importance and a change of climate should always be considered in every case when possible. The author's personal views about "internal cell traumas" are of interest as he attributes these to conditions of dyscrasia such as uratic (?) diatheses and other metabolic disturbances. The general constitutional level of the organism is, according to Schmidt, not without influence as a predisposing cause, and this factor, after operative removal of malignant tumors, should always be considered.

The special part of the book is devoted to the description of malignant diseases of the various abdominal viscera and the kidneys. This is followed by a large number of case histories personally observed and studied by the author, which are arranged in systematic order to correspond with the text of the previous portion. Whenever possible the operative or autopsy findings are reported. The book is of particular interest to all physicians and surgeons and the translator is to be commended for publishing the English edition of the same.

SCIATICA—A Fresh Study. By WILLIAM BRUCE, M.A., LL.D., M.D. (Aber. With Notes of Nearly 700 Cases. Price $1.75. New York: William Wood & Company, 1913.

THIS book gives an historical survey of the different views held on the nature of this disease by Sir William Gowers, Dr. Lawson, and others. In contradistinction to these the author believes that the hip joint is invariably involved in the vast majority of the cases of sciatica. With this view in mind the author describes the examination of the patient, etc., and gives the record of 676 cases. Authorities on the *x*-ray examination of the hip joint are quoted testifying to the involvement of the joint. A short chapter is devoted to treatment. More than one-half the volume of the book is taken up by the appendix dealing with the anatomy of the hip joint and the histories of 691 cases that have been treated. A bibliography and 18 plates complete the book.

# Society Reports.

## THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, Held February 23, 1914.*

THE PRESIDENT, DR. T. PASSMORE BERENS, IN THE CHAIR.

**Saratoga Springs and Its Mineral Waters.**—Dr. ALBERT WARREN FERRIS read this paper and gave a lantern slide exhibition of scenes in and about Saratoga. He reviewed the history of the locality from the time when it was in the possession of the Indians and said that the healing properties of the waters were first reported by Sir William Johnson, who in 1767 was cared for at High Rock Spring by friendly Indians when suffering from an old gunshot wound. This report was supposed to have actuated General Schuyler to cut a roadway to the Spring through twelve miles of forest, in 1783, and to erect a shelter for himself and family while for several weeks they used the water. From that day to this Saratoga had been a more or less popular resort, reaching the position of perhaps the best known and most fashionable spot in America about one hundred years after Sir William Thomson first set the fashion. Dr. Ferris sketched briefly the history of the era of pumping the waters by commercial companies, and wasting them after separating the carbonic acid gas for the market, which robbed the springs of their energy, causing a rapid lowering of the water levels and so depleted the whole mineral water zone. Action of the Saratogians, led by the late Spencer Trask, Frank H. Hathorn, and others, resulted in a law prohibiting the pumping. For practical purposes the mineral waters might be classified as follows: Saline-laxative (including Hathorn No. 1, No. 2, and No. 3), Columbian, Flatwell No. 2, Ditch Well No. 2, Island, Shonts No. 3, Coesa, Peerless, Emperor, and Adams alkaline-saline (including Geyser, Pump Well No. 4; Minoneba, New Shonts, Clark No. 1, and Clark No. 2; the ferruginous or chalybeate, including Flat Well No. 2, Old Red, New Red, and Magnetic. Many of the waters fell into two of these classes. Of special value were the table waters, Geyser and Minoneba, the latter closely resembling Grande Grille Vichy. Prescribed as chosen for individual cases the waters were variously indicated for use in gastrointestinal disorders, gout, rheumatism, arthritis, anemia, and obesity. Some were admirably adapted for use in incipient kidney troubles, in neurasthenia, general fermentation from increase of acidity in the digestive tract, certain skin diseases, and in the elimination of various poisons from the body and the removal of certain exudations due to disease. Fortunately they had two things which closely resembled the spring No. 12, Nauheim, Germany, since they contained the same calcite and magnesite salts, and were therefore suitable for use in giving the Nauheim system for arteriosclerosis, certain other circulatory disorders, and some forms of heart disease. Their chief field of activity, however, would be in the domain of disorders of the digestive tract, in diseases producing tissue change, and in the reduction of obesity. The essayist said he would not dwell on the chemical constituents of the waters as they existed in composition, since full analyses were available in print. All the springs were radioactive. The Bureau of Mines, Washington, D. C., had reported that the radioactivity was due to dissolved radium salts and not merely to absorbed radium emanations, therefore they contained a permanent agent which would produce emanations indefinitely. Dr. Paul Haertl, the director of the laboratory at Bad-Kissingen, Germany, studied the situation thoroughly and stated that our springs were unequaled or at least unexcelled in the world, and he was a competent authority on the subject. His advice confirmed the conviction that the State must proceed at once to the erection of a large bath house and a central drink hall in the center of the village of Saratoga. Dr. Ferris described in glowing terms all the possibilities of the place, including a plan for a pine promenade and equipment and facilities as complete as those in Continental spas. He believed that many thousands of Americans would prefer to go to Saratoga for their cure rather than to undergo the expense and fatigue of an ocean trip, to subject themselves to the vicissitudes of an unknown climate, and dwell for a considerable period in a country whose language they could not speak. Over 7,300 physicians throughout the State had been circularized in order that they might all be informed of the beginnings at Saratoga as well as of the vast enterprise projected. The plans for the immediate future include the erection of a large bath house with administration building and power house and also a central drink hall, to which would be conducted all the available drinking waters in the village proper and in the Geyser district, so that the invalid would not be obliged to go to the source of the various springs whose waters were prescribed for him. The center drink hall would permit the service of waters, either hot, cold, or warm, as prescribed by the physician, and would tend to secure obedience to the physician's order to drink the water slowly. Baths could be had at low prices or free to those whose means were limited. Dr. Ferris urged the cooperation of all physicians in furthering the execution of these plans.

**The Phenomenon of Pathological Antagonism; Its Relation to Diabetes Mellitus.**—Dr. HENRY S. STARK read this paper. (See page 645.)

## NEW YORK PSYCHIATRICAL SOCIETY.

*Regular Meeting, Held January 7, 1914.*

THE PRESIDENT, DR. CHARLES L. DANA, IN THE CHAIR.

**Election of Officers.**—The following officers were elected for the year 1914: President, Dr. William L. Russell; Vice-President, Dr. L. Pierce Clark; Secretary-Treasurer, Dr. Swepson J. Brooks.

**Report of Committee on National Hygiene Movement.**—Dr. STEWART PATON presented this report in which he stated that the work of the committee had been divided into three fields. 1. Original inquiry, which should be interesting and instructive, especially if followed out along the lines laid down by the Wisconsin Society. 2. Observations made in psychiatrical clinics. 3. Observations made of the work in out-patient departments. He emphasized the importance of popular education and believed that following this there would be remarkable success in the work. The popular education committee had taken up an educational program. The importance of this part of the work had been shown during the past year in what had been accomplished in New York, Pittsburgh, Philadelphia, Boston, Raleigh, Texas, and Rutland. It was surprising to see the intelligent interest that had been taken in this subject. Great success was attained in Rutland by inducing the Governor to be present. Dr. Patton said he did not see just why the presence of the Governor should be so effective, but he had been told that there was nothing which would help the movement along more, and in Vermont this seed had borne fruit. In Raleigh, N. C., they had a very interesting meeting. Mr. Daniels of the United States Navy was present and took a direct and personal interest in the movement. So it had been all over the country. He had been told that this field demanded an exhibit and several experts who should explain this national hygiene movement. In the plan of organization the national society would supervise the State societies. It was strange that there should be so much difficulty in finding men who had sufficient medical knowledge to control some of these societies. It was essential that the work should be controlled by medical men. The medical men should exert an influence in dealing with this problem and should do what Rousseau said years ago in regard to the educational system. First, they should find out what was the adult's capacity; second, they should find a level at which he could adjust himself. They should also deal with the problem of medical education. The young men should be trained so that they were well prepared to enter a university at the age of seventeen or eighteen, instead of twenty-two or twenty-three.

Dr. WILLIAM L. RUSSELL said that one aim of the national hygiene movement had been accomplished. This was to interest the United States Government in its objects. The United States Public Health Service was now willing to publish and distribute documents free of charge, and was contemplating entering the field itself.

Dr. L. PIERCE CLARK said the New York public schools in the ungraded class division were now making a permanent exhibit upon the psychopathies of school children and the training and prophylactic treatment of the same. The exhibit with a proper equipment of lecturers was to visit the several normal schools and colleges of the State so that the pupil teachers might be informed of the problem to be solved in teaching psychopathic children. This school museum should

form an integral part or cooperate with the National Hygiene Exhibit, and steps for the affiliation should be taken at once so that the principles in both exhibits might harmonize.

Dr. CHARLES L. DANA emphasized what had been said about the State Societies of Mental Hygiene and believed that they should be organized carefully and along proper lines. The committee was prepared to spend $11,000 in establishing these mental clinics, outside of dispensaries. Personally he did not know where the money was to come from unless through lectures in connection with traveling museums; it seemed to him that the plan of organization was on an expensive basis and might ruin the movement.

**Retarded and Feeble Minded Children.**—Dr. L. PIERCE CLARK presented this report, which included a rough draft of a bill for legislative enactment calling for a State survey of the feeble-minded, with the intent that such a body might formally recommend a permanent State commission to have entire charge of all the feeble-minded in the State. The society ordered and empowered the committee to continue and to cooperate with other agencies interested in this legislative movement.

**The Treatment of Cases of Mental Disorder in General Hospitals.**—Dr. PHILIP C. KNAPP of Boston read this paper. He said that in the various discussions in Boston of the proper disposition of cases of incipient and obscure mental disease before the establishment of the Psychopathic Hospital, when it was suggested that such cases might be sent to the City Hospital, the trustees always opposed it. One of the rules of the hospital was that alcoholic and mental cases were not received. In their last report, however, the trustees stated that one of the advantages of the new neurological services was that it gave an opportunity for the proper care of psychopathic cases. In spite of the rules there had always been a considerable number of cases in the hospital who showed some degree of mental disturbance, as was inevitable in every general hospital. They were not welcomed and were often badly treated, restraint both mechanical and by drugs being employed unnecessarily. The neurological wards at the City Hospital received about four hundred patients yearly. The wards were open and from them a few single rooms opened, but there were no locked doors. Out of 785 patients admitted during the writer's term of service 74 were diagnosticated as one of the forms of mental disease (dementia præcox, senile dementia, general paresis, maniacal depressive insanity) and 93 showed some phase of alcoholism. Many other cases, however, showed more or less mental disturbance; many cases of neuritis had Korsakoff's syndrome; cases of organic brain disease were often mentally affected, as well as the cases of hysteria, epilepsy, chorea, etc. At least one hundred cases a year showed considerable mental disturbance and about forty were committed each year. Many cases, of course, were quiet and well-behaved, but others were much disturbed; they had also to deal with extremely suicidal cases, the most violent epileptic mania, and patients who had to be tube-fed. Such cases used to be restrained, often without necessity. Under existing conditions mechanical restraint was sometimes necessary, but the writer and his colleague, Dr. Thomas, had succeeded in reducing the amount very greatly, and had used sedative drugs very sparingly, very rarely resorting to the more powerful drugs. The result had been satisfactory. Patients were much less disturbed when restraint was not employed, and there had been no suicides, no escapes, and no serious act of violence in four years. The fact that the hospital had no legal right to keep such patients against their will had caused no difficulty. The reception and temporary care of such patients in a general hospital, even without locked doors and a hydrotherapeutic plant, had proved perfectly feasible. The advantages were that it proved an easy way of dealing with cases of acute onset, or those that fell in the hands of the police, without any delay or legal formality. It afforded an opportunity to study obscure cases and to give the family time to realize the patient's condition, to make up their minds to commitment if necessary, and to select a suitable hospital. Finally it permitted the treatment of cases of short duration in the hospital until they recovered, thus sparing them the stigma of being officially judged insane, a matter of some significance in estimating a man's efficiency, or, in some States, of deciding upon matrimony. The writer cited several such cases, and emphasized, in closing, the duty of all hospitals to receive and care for such patients; but unless they were put under the care of competent neurologists, who should have full control of them, they could not be successfully treated.

Dr. AUGUST HOCH said he was much interested in Dr. Knapp's paper which demonstrated the possibility of opening the general hospital wards for the reception of patients suffering from mental disorder. It was an important sign of the times that the mental abnormalities were brought into closer contact with medicine in general, that their importance to the general physician was receiving more recognition, and that the duties which the general hospital had in this direction were being more appreciated. All these changes were bound to develop fully. It might not be out of place to mention the fact that Dr. William Russell had insisted for some years on the duties of the general hospitals in this direction.

Dr. WILLIAM RUSSELL said he had been struck by the experience of some in open wards and it seemed impossible that in four years they had had no accidents at all, nor should there be any when proper precautions were taken. Dr. Russell asked Dr. Knapp if there had been any accidents.

Dr. KNAPP replied that thus far there had been no accidents in the service, and although there had been escapes from the other services, there had been none from the neurological service. Delirious cases in other services, if primarily medical or surgical cases, usually remained in those services until the primary trouble cleared up. The neurologist was called in consultation at times, and, if he advised, the case might be transferred, but this advice was not always followed. He had often advised stopping alcohol in alcoholic cases, but sometimes the alcohol was kept up, against his advice, and the patient died of a "wet brain."

Dr. M. S. GREGORY said that the man who was the greatest source of difficulty in a general hospital was the medical man. He did not pay much attention to these conditions. He was not interested in mental disease and cared little about it. Therefore, proper provision should be made for the care of these patients. The work outlined could be carried out in a few hospitals. He believed in the temporary care of these patients.

Dr. L. PIERCE CLARK asked Dr. Knapp if it were not possible to get physicians and nurses from the hospitals for the insane who intended to go out in private practice to go into the general hospital for a certain length of time and there learn some of the difficulties that they would necessarily meet later in private work.

Dr. FLAVIUS PACKER said that while he was visiting the Medical Inspector of the State Hospital Commission he learned that mental cases would not be taken into the hospital at all, but were cared for in a room over a saloon. This state of affairs existed at Dobb's Ferry.

**On the Mechanism of Some Cases of Manic-Depressive Excitement.**—Dr. C. MACFIE CAMPBELL of Baltimore read this paper, which presented the results of investigations on manic-depressive insanity along the lines outlined in two previous communications to the society. Emphasis was laid on the necessity of going beyond the formal characterization of the disorder and studying the meaning of the whole reaction in the light of the situation out of which the attack developed. For this purpose careful observation and analysis of the patient's utterances were required. The writer described four illustrative cases, which led to the following conclusions: In many cases of manic-depressive excitement the onset of the attack became intelligible in the light of the careful reconstruction of the whole situation out of which the attack had developed. The difficulty of adjustment which led to the manic attack was much less deeply seated than in dementia præcox and allied conditions; the conflict was much more clearly realized by the patient, the flight into the psychosis coincided with the relaxation of efforts which were recognized as inadequate to deal with the actual situation; the cessation of this struggle permitted the frank expression of repressed elements. The elated mood and exuberant activity of the manic patient were thus partly explained. It was important to study closely the content of the utterances of the manic in order to understand the meaning of the situation leading to the attack; this line of investigation included an accurate estimate of the equilibrium of forces which made up the patient's personality, and involved a thorough study of the individual's development. A thorough review of the above factors might put the patient in a better position with

regard to the possibilities of avoiding further attacks.

Dr. August Hoch said it was interesting to listen to a study of manic-depressive insanity in which an attempt was made to understand the mental forces at work. He had been much impressed by the analysis which Dr. Campbell presented, and by his formulation of the mechanism of manic states. But he wondered whether his theory that we were dealing essentially with what might be called an escape reaction was generally applicable, and whether it was not necessary, in making a theory of manic states, to take more cognizance of the meaning of the normal reaction of elation, which certainly was not as a rule a mechanism of escape. In considering this question, Dr. Hoch said he had come to somewhat different conclusions, which, however, were hardly sufficiently crystallized to be spoken of.

Dr. Smith Ely Jelliffe said he was in sympathy with Dr. Campbell's point of view. Such reports as Dr. Campbell had given were the only kind of studies that really counted. The presentation showed careful study. These were definite dynamic studies. Dr. Jelliffe said he felt that the mild manic-depressive cases, some possibly being confused with what Freud had described as anxiety hysterias, offered a very fruitful material for psychoanalytic study and treatment. His experience in the past two years had covered a number of instances of mildly depressed patients, who had been, he believed, greatly benefited in that they had obtained by psychoanalysis a real insight into the dynamic factors of their psychosis. The introverting moments interested him a great deal, and he had found many cases, both with excitements and depressions having the factors Dr. Campbell mentioned and emphasized, showing situations similar to those mentioned by Dr. Campbell, and which proved the point of departure from healthy to psychotic mental adjustment.

Dr. Campbell said, in closing, that it was difficult to cover the ground in a brief communication. He had endeavored to keep his presentation as close to clinical observation as possible, and to show certain demonstrable causes which had much to do with the onset of the manic attack. The paper did not profess to deal with every aspect of the subject, as, for instance, heredity. What he intended to emphasize was that the manic excitement became more intelligible in the light of a reconstruction of the various forces which made up the balance of the individual's life, that the attack to a certain extent represented the abeyance of repressing forces, the relief of tension, and that the expression of the repressed forces was responsible for a good deal of the elation and exuberance of the patient. In estimating the tension at the period of onset, the intensity of the crude *libido* was something which could not be ignored. The manic patient was very frequently aware of the nature of the conflict which led to the attack.

## NEW YORK ACADEMY OF MEDICINE.

*Regular Meeting, Held March 5, 1914.*

The Vice-President, Dr. L. Emmett Holt, in the Chair.

This meeting was held under the auspices of the Section of Medicine.

**The Value of Tests for Renal Function in Early and Advanced Bright's Disease.**—Dr. R. Fitz of Boston presented this communication. He stated that in view of the different types of nephritis and the impossibility of predicting in the individual case by clinical study alone what course the disease would take, or what anatomical changes would be found at autopsy, methods had been devised for estimating the renal function in order to make possible an early diagnosis of existent kidney disease and to offer information in regard to its prognosis and treatment. In reviewing the work which had been of value in the early diagnosis of abnormal renal function, the essayist referred to that of Schlayer who found that in tubular nephritis the renal vascular system reacted to vasodilators and constrictors normally. The urine, however, was dilute, and the kidney was unable to concentrate and excrete sodium chloride when it was injected intravenously. In vascular nephritis, on the other hand, the kidney's concentrative powers mere unaffected, while the vascular response to vasomotor stimuli was lost or exaggerated. This led him to determine whether the excretion of other substances in addition to sodium chloride might be used as a measure of efficiency of the vascular or tubular apparatus of the kidney to replace observations with the oncometer. In tubular nephritis the amount of fluid excreted was not remarkable but in vascular nephritis it varied directly with the vascular functional condition. The amount of urine obtained was one index to glomerular function. Voit discovered that if lactose was injected into an animal intravenously or subcutaneously the entire amount could be recovered in the urine. Schlayer found that in experimental nephritis intravenous injections of this sugar were only well excreted when the renal vascular system was normal, and were held back when the glomeruli were damaged. Schlayer adopted the excretion of water and lactose as indicators of renal vascular activity, and that of sodium chloride and potassium iodide as measures of tubular activity. By using these various tests Schlayer claimed to be able to distinguish certain types of acute and chronic nephritis and to have found their distinguishing characteristics to be sharply demarcated. Vascular nephritis, whether acute or chronic, was characterized by a delayed lactose excretion, by oliguria or polyuria, depending on the sensitiveness of the renal vessels, and by normal chloride and iodide excretion. Tubular nephritis was shown by a normal water and lactose excretion but with delayed chloride and iodide outputs. All grades of mixed functional disturbances were found between these two extremes. In a general way the tests pointed out the severity of the disease, and, since they were all delicate, they often showed functional changes before clinical signs of nephritis developed. The essayist then reviewed the different opinions held in regard to the anatomical changes producing these functional disturbances. The author believed that by following the excretion of these substances used in the tests, and by adding test amounts, it was possible to discover an abnormal renal function before marked clinical signs of kidney disease were manifested and cited a number of cases from the Peter Bent Brigham Hospital, of Boston. They proved on the whole that Schlayer's tests were significant, chiefly because they showed early functional disturbances in the kidney, and by repetition illustrated the rapidity of development of an early disease. Whether vascular and tubular function on an anatomical basis could be differentiated in Bright's disease with the same definition as in experimental toxic nephritis remained to be determined by a careful study of more clinical and pathological material. In advanced nephritis these tests were less useful. Dr. Fitz expressed the opinion that the phenolsulphonaphthalein test as applied by Roundtree and Geraghty had given the most valuable aid to the estimation of total renal function which was known at present. Roundtree and Geraghty had shown from careful studies in nephritis that the amount of phthalein excreted varied in direct proportion to the severity of the disease. In fatal uremia only traces of the dye were found in the urine, while in mild nephritis the amount recovered was nearly normal. In cardiorenal disease where the heart was chiefly at fault and the kidneys were congested without a marked nephritis, a low phthalein output might be observed at first, rapidly rising as the circulation was restored, while, if severe nephritis was present, no change in the phthalein excretion accompanied the improved circulation. In addition to its accuracy the test had the advantage of being rapid and so simple that it could be used by the general practitioner. The test had been used successfully by so many observers that its value must be accepted as a fact. In a few cases, however, the excretion of the dye gave unreliable information. This appeared to be because a diseased kidney might be permeable to one substance while it was impermeable to another. Bard and Bonnet, in studies on renal function in which potassium iodide and methylene blue were used as tests, found that in interstitial nephritis the excretion of both substances was faulty, in epithelial nephritis the kidney was hyperpermeable for both, and in secondary interstitial nephritis the methylene blue excretion was normal or increased, while that of the potassium iodide was diminished. Pepper and Austin had lately called attention to a case of nephritis with marked albuminuria, cylindruria, and edema in which the phthalein output was normal, and Baetjer reported nearly a similar case. Foster illustrated the difficulty of prognosis by the use of any one kind of functional test, giving examples of cases which died of uremia with a practically normal phthalein output shortly before death. However, on the whole, the phthalein test was of great

value, but in order to judge the degree of renal insufficiency with accuracy more than one test must be used. Of substances studied in the blood of nephritics the concentration of the incoagulable nitrogen and urea had been found to be of most importance. Yet cases occurred in which blood nitrogen and phthalein were both normal and chloride retention was an important factor in the disease. Finally acidosis had been shown to exist in uremia. Since no one test was perfect in determining total renal function, cases must be studied from several points of view. A rational dietetic treatment could be given in individual cases based on the conditions disclosed by the study of the kidney's selective excretory capacity.

**The Value of Renal Functional Tests to the Surgeon and the Limitations of these Tests.**—Dr. JOHN T. GERAGHTY of Baltimore presented this paper. He declared that in ascertaining the functional capacity of the kidney, judicious selection of tests was the key to the maximum amount of information from the minimum expenditure of time and energy. The number of tests was now so large that it was impossible to utilize all in any one individual case. It was not necessary, moreover, since all the available information was forthcoming at times from a single test or from a proper combination of a small number of tests. Only through familiarity with the reliability, value, limitations, peculiarities, and significance of the findings of each test in various types of disease was the most profitable selection of tests made possible. Certain tests, such as the lactose and the chloride tests proved of great value to the internist, but were practically valueless from the standpoint of the surgeon. Some tests were valuable for an estimation of total function, but could not be utilized in conjunction with ureteral catheterization. Other tests might be of no value for the estimation of total function, but might be very valuable in conjunction with ureteral catheterization for estimating the relative functional ability of the kidneys. Urea estimations of twenty-four hour output gave, as a rule, information of but little value, but urea estimations of catheterized specimens gave a very accurate idea of the relative amount of work done by each kidney. Renal functional tests had already proven their great value to the surgeon in two types of cases. First, in the surgical diseases of the kidney secondary to obstruction in the lower urinary tract, and, secondly, in the unilateral and bilateral surgical diseases in association with ureteral catheterization. Dr. Geraghty said that in a former communication Dr. Roundtree and he had called attention to the fact that patients with renal changes resulting from obstruction in the lower urinary tract were frequently the subject of hydronephrosis, pyronephrosis, pyelonephritis, pressure atrophy, and the resulting changes in functional activity, and that the urine output, urea and total solids, might be practically normal and yet the patient be on the verge of renal failure which would surely be precipitated by any radical surgical interference. The phthalein test was shown to be of value in all of these cases and to allow of differentiation between those cases with severe renal damage and those in which the renal involvement was slight. It was further shown that the marked improvement of the renal condition and the decreased operative risk which followed the adoption of preliminary treatment, either through the use of an in-lying catheter or suprapubic drainage, was the result to a large extent of the improvement of the renal functional capacity. It was claimed that the test made it possible to determine the cases suitable for operation and also to determine in any given case the most propitious time for surgical intervention. Subsequently a number of tests had been utilized in order to determine if any individual test or any combination of tests furnished information other than that derived from the use of phthalein. Of the excretory tests, lactose, diastase, and urea were employed, and of the retention tests, cryoscopy and blood urea. The lactose test was employed in a series of about twenty-two cases, and in only two was a positive test for sugar obtained. The lactose test in this type of case had proven of little value from a diagnostic standpoint and of no value in relation to prognosis. The prognostic significance of this test in cases of urinary retention as compared with chronic nephritis was striking. The absence of glycosuria following the injection of lactose or its elimination in mere traces in chronic nephrits indicated renal derangement of a severe degree. In the series of cases in which the diastase estimations were made, in some instances with severe renal damage, the diastase content was normal. In a few cases in which the phthalein and the clinical findings showed only slight renal impairment the diastase was markedly decreased. In the majority of instances of disease a decreased diastatic activity was present, but no constant or definite relationship between the diastatic activity and the true renal function existed. Where, however, a complete absence of diastase in the urine occurred, it apparently indicated an extremely bad renal derangement. Urea estimations of the twenty-four hour output gave information of but little value. In the second group of tests, namely, those of retention, a consideration of what was regarded as the normal limit seemed advisable. From their observations it semed advisable to place the limit of normal at 0.55 grammes for urea and —60 for the freezing point. In every case in which a freezing point lower than —60 was encountered, except in one case, the renal function was seriously involved. The blood urea had proven a better index to the renal condition than cryoscopy, and in several of their cases afforded indications of cumulative phenomena earlier than cryoscopy. In no instance was a normal blood urea associated with markedly decreased phthalein, while, on the other hand, in every instance in which the phthalein was high the blood urea was normal. From these results it seemed that their previous claim in relation to the value of phthalein was well founded. This undoubtedly afforded the truest index if the functional capacity of the kidney in this group of cases. In no instance were its findings incompatible with the clinical condition and subsequent history. Diastase and urea were of about equal value and were unreliable indices to renal functional capacity generally, but, where very low values were persistently indicated, they had some prognostic significance. Cumulative phenomena did not occur in the presence of good renal functional capacity and consequently the tests were unnecessary where phthalein was normal. The tests simply indicated the renal function and it depended on the operator what risks he was willing to assume, the probabilities of fatalities increasing as the renal function decreased. They found, however, that, when they had low function which otherwise might be unrecognized, that preliminary treatment in most instances allowed a regeneration of function, which would be indicated by the test, and enabled the patient later to undergo the greater operation of prostatectomy with less risk. In regard to the employment of functional tests in association with ureteral catheterization it seemed desirable to know (1) the total or combined renal function without ureteral catheterization, (2) the relative function, and (3) the absolute functional value, if possible, of each kidney. In this class of cases the shortcomings of most of these tests were very evident, since they gave only a relative functional value of the kidneys. The employment of functional tests in association with ureteral catheterization was attended with two great difficulties, which in certain cases made it impossible always to obtain all the desirable information from any one test, namely, inhibition of function and leakage around the ureteral catheter. Any discrepancy due to inhibition could be determined readily through the determination by phthalein of the total renal function without ureteral catheterization. Unfortunately the inhibition was not always equal on each side, and, under such conditions, one was not justified in accepting the phthalein or total urea from each side as the true index of the relative value of the two kidneys. In this connection diastase and urea per cent., together with the difference in the intensity of urinary pigment and consideration of the total phthalein, were of value. When inhibition occurred the urea per cent. and diastase had equal significance, but when inhibition was absent and leakage occurred diastase was more reliable, since it was not so readily affected through dilution. Phloridzen had proven of comparatively little value in their experience and added practically nothing to the information obtainable from the other tests. Unfortunately the problems presented were not always simple. Cases of bilateral diseases were encountered in which a knowledge of the real function became of absolutely vital importance and in which every source of information must be called upon before the proper line of procedure could be determined upon. In certain cases, particularly those of tuberculosis, it might be possible to introduce the catheter only on one side. In such cases one must depend to a great extent upon the information derived from function re-

garding the condition of the opposite kidney, as cystoscopic findings regarding the appearance of the ureteral orifice were frequently deceptive. Functional estimations had also proven of great value in the differentiation between pyelitis and pyelonephritis. In pyelitis the real function was practically normal while in pyelonephritis there was decreased function, depending upon the degree of destruction. It had enabled them to select with considerable accuracy cases of renal infection suitable for lavage. As to the limitations of functional tests, it should be remembered that functional studies revealed only the excretory capacity of the kidney; by themselves they did not make the diagnosis or settle the prognosis. They indicated only the functional value of the kidney at the time at which the test was performed, but could not of themselves indicate what the renal function would be to-morrow or next week. Furthermore, it did not always follow that an individual with urinary obstruction and a good renal function was necessarily from the standpoint of function a good operative risk. It was known from practical experience that this class of patients was an extremely dangerous one because ascending infection might occur, and did frequently occur, following operation. They should receive preliminary treatment either by the catheter or suprapubic drainage, notwithstanding the fact that they might have at the time when first seen good renal function. Functional tests were of the greatest value when used in conjunction with careful clinical studies, and, when employed with the proper regard for their value and limitation, furnished valuable information in diagnosis, prognosis, and selection of lines of treatment.

Dr. Edward L. Keyes, Jr., said it was rather dangerous to discuss these papers, for after what he had heard from the laboratory side and from the clinical side the answer might be either "Yes" or "No." Yet there was a certain amount of reason for every man's opinion if only from a clinical point of view. He said he had had the opportunity of studying a number of methods for estimating renal function. He had been asked "What is meant by renal function?" It seemed to him the best answer was "Renal function means the excretion of solids dissolved in water." Dr. Geraghty showed a test which only estimated precisely how the kidney acted at a particular moment. The surgeon was not interested in that, but only in how the kidney acted when subjected to a surgical operation. Surgical criticism must depend upon the accuracy in prognosis and not so much in diagnosis. "How will the kidney withstand shock?" The way an operation was performed and the length of time employed were two important elements in the prognosis. Therefore, no two surgeons could expect to obtain the same data in making use of the test. After using various tests Dr. Keyes said he had come to rely more upon the phenosulphonaphthalein test.

Dr. Warfield T. Longcope said that the papers impressed upon all the importance of functional tests in investigating disease of the kidney. He considered several groups of cases. There was one group of classical cases which was very interesting with congestion of the kidney and with the accompanying kidney disturbances. In a fair proportion of these cases there was a broken compensation, reduced excretion, and so on. Within a few days, or a week or more, by improving the cardiac function the renal function would be improved. There was another group of cases with hypertension and some of these might be under observation for many years. There was a high blood pressure, cardiac hypertrophy, and attacks of convulsions considered to be uremic. In many of these cases the renal function would be normal. At autopsy little change would be found in the parenchyma but there would be found, however, extreme changes in the blood vessels not only in the kidney but in the vessels throughout the body. These were cases of vascular disease rather than nephritis as such. He hoped that the work of both the speakers would clear up the situation.

Dr. Nellis B. Foster said that the tests had their limitations. The ideal test would result from a metabolic study. Certain tests, such as the lactose and the chloride, were too delicate.

Dr. Martin W. Ware thought an error was made in functional tests where certain tests were applicable to medical cases and other tests were applicable to surgical cases when all had the same substratum. The test stood in the same position as many remedies for the same disease. What the surgeon wanted to know was what the kidneys were able to do. What they wished particularly to do was to lower the death rate from operations. Phenolsulphonephthalein as a test was acidometric rather than colorimetric. It was used as a measure to determine the degree of acidity of the urine.

---

SECTION ON PEDIATRICS.

*Stated Meeting, Held February* 12, 1914.

Dr. William P. Northrup, in the Chair.

Congenital Malaria.—Dr. Murray H. Bass read this paper in which he reported a case which he believed to be one of congenital malaria. He stated that it had been the consensus of opinion that malaria was probably not transmitted *in utero*. However, during the past few years a small number of cases reported by competent observers seemed to offer incontestible proof that, though a rare occurrence, malaria might be transmitted antenatally from mother to offspring. Meara reported the case of an infant born in the middle of October, at Massapequa, Long Island, whose mother and father had suffered from malaria in August, but who had apparently been cured in the course of a few weeks. Ten days after birth the baby, apparently well until that time, began to lose weight and seemed ill. When seven weeks of age the baby was admitted to Bellevue Hospital, where in the routine examination of the blood it was found loaded with malarial organisms. The child died in spite of vigorous quinine medication. Meara seemed to doubt the occurrence of intrauterine infection and evidently did not consider his own case as completely proven. The case reported by Beekel was one of quartan malaria in a child ten weeks of age, born at the end of September, and could not be definitely attributed to intrauterine infection owing to the time that had elapsed before the child showed symptoms and on account of the absence of any history of recent malarial infection in the mother. After a thorough search of the literature Beekel succeeded in collecting eleven cases of congenital malaria which seemed to be absolutely proven. Dumollard and Vialet, in 1909, reported the case of a woman seven months pregnant who was attacked by a severe type of malaria. In spite of large doses of quinine her fever continued and in a precipitous labor she gave birth to a child which lived only one hour. The placental blood, the blood from the cord, and the heart blood all showed plasmodia of the same type as those in the maternal blood. The labor had not been attended with hemorrhage. A. Laffont reviewed the whole subject, reported a case of his own, and concluded that the parasite might be transmitted from mother to fetus, that the rebellious types were not always those transmitted, and that hereditary malaria might be divided into two types, the congenital which occurred in the embryo or fetus, and true hereditary malaria which attacked the fetus but developed in the newborn, the child, or the adult. He believed that congenital malaria might be acute, chronic, or latent. The most recent reported case was that of Tissier and Brumbt. This case occurred in a woman in Algiers. She had an attack of malaria in January and a recurrence in May of which she was apparently cured. In October she gave birth to an apparently healthy child in Neuilly, France, having removed from Algiers on account of the malaria. When nineteen days old the infant developed fever of the tertian type, and plasmodia were found in the blood. It was stated that it was practically impossible for the child to have been infected after birth since malaria and mosquitos were unknown in Neuilly in October. They believed that the infection occurred either at the time of birth or *in utero*. To these cases Dr. Bass said he wished to add one of his own, an infant born in New York City at the end of December of a mother who had suffered from untreated tertian malaria for four weeks during the fifth month of pregnancy. The infant was taken ill at the age of four weeks. The symptoms, pallor, irritability, loss of weight, and green stools, caused the mother to bring the baby when seven and one-half weeks of age for medical advice. An extreme anemia and an enlarged spleen led to a blood examination with the finding of tertian malarial plasmodia. Rapid recovery took place under the administration of iron and quinine. Though it might be admitted that there was no way of definitely proving that the case was one of congenitally acquired malarial infection, the evidence all seemed to point toward that conclusion, for it was incredible that

in that portion of New York City, 120th Street, there should have been mosquitos capable of transmitting malaria in the midst of winter. To this case might be added another. About eight years ago a woman who had suffered from malaria some time previously gave birth to an apparently healthy child. Plasmodia having been found in the mother's blood, that of the infant was examined immediately after birth and the plasmodia were found. After a few doses of quinine these parasites disappeared. Dr. Bass said that it was well known that malarial infection might remain latent for a considerable length of time in the adult and he could see no reason why this had not occurred in the case he had reported. In view of the fact that post-natal infection seemed to be positively excluded, he believed that this might be considered a true case of congenitally acquired malaria. Several months afterward this child died in convulsions during an acute attack of gastrointestinal intoxication, having been ill only twenty-four hours. At autopsy the only gross finding was an enlarged thymus. There was no hyperplasia of the lymphoid tissues at the base of the tongue, or in the follicles of the intestinal tract. The spleen was normal in size and consistency and the mucosa of the intestinal tract showed no erosions or injection. Microscopically the liver showed a slight grade of beginning diffuse necrosis, the kidneys a moderate acute nephritis, and the spleen some hyperplasia of the Malphigian bodies and considerable pigment through its substance. No malarial parasites were found in the spleen. A fact worthy of note was that all the babies appeared to be healthy at birth and this did not speak in favor of the infection occurring during pregnancy, but rather in favor of its having taken place during labor; however, we were not in a position to say how the infection took place.

Dr. Floyd M. Crandall said that if the congenital transmission of malaria was possible it was strange that it did not occur more frequently, still the case reported was pretty positive and went to prove the possibility of such transmission. Dr. Crandall referred to a case which he had reported many years ago, in 1892 he believed. In this case the mother had had a malarial paroxysm and the child had been born during the sweating stage. The following morning the child appeared to be all right. In the afternoon, eighteen hours after birth, the infant became blue and pinched in appearance and it was thought that it was dying when he was sent for. He found that the child had a temperature of 102° F. The same thing occurred on the following day, and the child had four such attacks, each lighter than the preceding one. In those days they knew little of the plasmodia or of blood examinations, but he had attended a meeting where he had heard Dr. Walter B. James read a paper on the subject, so he took blood cultures and had them examined on the third day and the plasmodium was found in the blood of both mother and child. Dr. Crandall said that he did not see, all things considered, how this case could be other than a congenital one.

Dr. Charles Herrman said that twelve years ago he had seen a case which he believed to be congenital malaria in the Italian Colony in Harlem known as "Little Italy." The mother had recently come from Italy and gave a clear history of malarial attacks. The baby was three weeks old. It did not have distinct chills, but had attacks of cyanosis followed by fever. Plasmodia were found in the blood and under quinine treatment the attacks disappeared. Although one could not be absolutely certain the case was in all probability congenital.

Dr. William P. Northrup recalled the case of a baby two weeks old that had malaria. The child was given ten grains of quinine and lived.

**Tropical Diseases in Children.**—Major Frederick F. Russell, U. S. A., presented this communication. He stated that children's diseases in the tropics were very similar to those in this latitude with a few exceptions. Scarlet fever, diphtheria, mumps, and whooping cough were not common. Measles was more often seen, and chicken pox was quite prevalent. Smallpox was so general in most places in the tropics that it was practically a disease of childhood. The more frequent diseases were the diarrheas and dysenteries, eczema, furunculosis and prickly heat, malaria in all its forms, infections, with intestinal parasites, and above all syphilis, both acquired and congenital. In the Far East they had also beriberi, yaws, and at times cholera and the plague. Infections with intestinal parasites were most important, because of their harm to the general health. With but few exceptions tropical cities were backward in sanitation and they had the same sort of infestations as were noted here fifty or sixty years ago. The commonest worm was the *Ascaris lumbricoides*, almost every native up to middle life being infected. It was customary to administer santonin and calomel to children about twice a year as a routine measure. As an instance of the effect of these parasites on the general health Major Russell cited a prison which had had a very high death rate which had resisted all sanitary reforms. It was found that the majority of the prisoners were infected with helminths. Following the general use of anthelmintics, the sick and death rates from all causes showed a remarkable improvement which had since been maintained. The most important nematode among children was the hookworm, *Ankylostoma duodenale* or *Necator americanus*. In countries where it was prevalent almost every native child was infected. The carrier state was frequently encountered absolutely without symptoms; this might be partly due to the development of immunity but more often it depended upon the small number of helminths present. *Oxyuris vermicularis* was rather more prevalent than in the temperate zones. The tape worms and flukes were also found, but the one of most importance was the dwarf tape worm, hymenolipis nana, which occasionally existed in almost unbelievable numbers and produced a variety of symptoms. The almost universal presence of helminths made the examination of the stools of more importance than the examination of the urine. It was absolutely essential to have some workable system for the collection and examination of feces. The specimen did not have to be quite fresh unless examination was to be made for entameba. Aside from the strictly human parasites, those of the dog and the pig were frequently found in children. The question of infection and reinfection was important and involved the instruction of all the families in personal hygiene. The duration of life of most of the parasites was short, one or two years at most, and if reinfection could be prevented they would disappear from the tropics as they had from the North. Malaria was of great importance in children as they were unable to protect themselves from the mosquito and their delicate skins made infection easier than in adults. The malarial index of a district was readily ascertained by noting the percentage of children with easily palpable spleens. All varieties of malaria occurred and the clinical course of the disease was more often atypical than not. Examination of the blood for malaria was also a routine procedure in the tropics. Syphilis, especially in seaport towns, was extremely common and compared to the disease in the North seemed mild and amenable to treatment. Yaws, the younger sister of syphilis, was more interesting. It was a chronic, specific, infectious disease characterized by an eruption of strawberry-like tubercles and more or less constitutional disturbance. It was caused by the *Treponema pertenue* of Castellani, an organism morphologically indistinguishable from the spirochete of syphilis. It had been shown, however, that yaws was a distinct disease entity and not a form of syphilis. The most interesting point about the disease at present was its successful treatment by salvarsan, one dose usually bringing about a complete cure. One of the most interesting and important diseases of the East was beriberi. For years an infantile form had been recognized in breast fed infants. A typical case in an infant occurred in the following manner. A young infant two or three months of age, previously healthy and well nourished, was suddenly seized with paroxysms of pain during which it straightened out the body and became rigid, the abdominal walls and epigastrium becoming tense and hard. The child cried constantly, the face became cyanosed, and the veins of the neck became turgid. The pulse was small and hard. The paroxysm passed off only to recur again and again until death supervened, which was usually within a few days or even a few hours. A chronic form of beriberi with gradual onset and sudden termination was also seen. At autopsy the same lesions were found in infants as in adults. There was extreme dilatation and hypertrophy of the right heart, hydropericardium, degeneration of the vagi and of the cells of the right cervical ganglion, and in most cases extensive subcutaneous edema. The singular point about this disease was its high mortality among breast fed infants. In 1905, 65 per cent. of the mortality among infants was among the breast fed and only 20 per cent. among those artificially fed. Fifty-six of the total infant

mortality of Manila was caused by this disease. It had been shown that beriberi was caused by highly milled white rice and this gave the key to the treatment of the disease in infants. An alcoholic extract of rice bran was prepared and fed to the children, the breast feeding being continued. The improvement was marked and immediate. At the end of the week or less the patients were practically cured. Chamberlain and Vedder had demonstrated conclusively that beriberi was not an intoxication but a deficiency disease. Its eradication was now only a matter of time, and of educating the rice-eating peoples to select the right sort of rice. Tetanus was so prevalent in the tropics that one had to be careful even in giving a hypodermic of morphine. All the bacillary forms of dysentery were also common; the same organisms and the same symptoms were found the world over. Amebic dysentery was also seen but not so commonly. Bilharziasis infection was common in China, Japan, and the Philippines. The principal habitat of the worms was in the portal vein, from whence they descended to the rectum and the bladder and worked their way through the walls of the intestines; the lesions thus produced sooner or later proved fatal, as there was no known efficient anthelmintic for these parasites. The strongyloides was of no particular importance except as an indication of the hygiene of the people. Kalaazar was found in both children and adults and was characterized by great emaciation, enlarged spleen and liver, and often edema of the lower extremities. The parasites causing the disease was the *Leishmania donovani*. The disease ended fatally. Major Russell said a new interest had been awakened in amebic dysentery since the introduction of emetine. After five or ten doses of emetine administered over four or five days there was an apparent cure, but most of the cases relapsed. In a patient who was gaining and had normal movements one frequently found enormous cysts in various stages of development. They developed four nuclei and as long as they persisted treatment must be continued. Major Russell illustrated his paper by an interesting lantern slide demonstration.

Dr. William P. Northrup said that the paper had been exceedingly interesting and that during the reading he had been especially interested in noting the resemblance of beriberi. to scurvy.

Dr. W. T. Longcope said he should like to know how the diagnosis of the cyst form of ameba in the stools could be made with certainty. In the fresh state there must be considerable difficulty in differentiating the cyst forms from epithelial cells, and since it might be possible that these encysted amebæ might be present in certain unexplained cases of chronic diarrhea in this locality, it seemed important that they should know exactly how the diagnosis of these forms might be made.

Major Russell replied that the diagnosis of the cysts of amebic dysentery was not difficult if one used the staining method of Schaudinn. Of course it took some experience but no epithelial cell had a nucleus like that of the cysts. The nucleus of the epithelial cell was larger and never multiple, while the amebic cysts might have four nuclei.

**Pellagra in Children.**—Dr. W. J. MacNeal in the absence of Captain Joseph F. Siler gave this talk which he illustrated with lantern slides. He said that pellagra was not a very important cause of serious illness or death in children, but the common occurrence of this disease in children was a very important feature of the general problem of pellagra. With regard to the manifestation of the disease in children, the skin lesions were similar to those in adults. They were well marked in children. The gastrointestinal symptoms, pain and acute or subacute inflammation of the digestive tract, were found in children as in adults. The involvement of the nervous system was, however, not so marked in children as in adults. One seldom saw the toxic phychoses that were met with in adults. In showing illustrations of the lesions, Dr. MacNeal called attention to the tendency of these lesions to girdle the wrists and said that the statement had been made that when this occurred the patient would die. He also called attention to the bilateral symmetry of the lesions and to the fact that they were more extensive where the skin was exposed to the sunlight. Absence of sunlight did not inhibit the progress of the lesion but delayed it. In children the feet were more commonly involved than in adults. When the lesions ceased to progress there was an increase in the severity of the gastrointestinal condition and of the general toxemia. Dr. MacNeal said that he would not confine himself to pellagra as it occurred in children, but would consider the general subject of pellagra. In a population of 6,600 people in endemic foci of the disease in South Carolina, there were 882 females and 1,005 males under ten years of age. During the two years 1912 and 1913 there developed in this population 91 new cases of pellagra and of these 23 new cases occurred in the female children and 25 in the male children. A statistical study of the food used in six villages, including about 5,000 persons, failed to reveal any consistent relationship between the use of any particular food and the occurrence of pellagra. A somewhat similar study of the location of domicile of old cases of pellagra in relation to domicile of the remaining population in these mill villages had shown that new cases of pellagra developed almost exclusively in persons living in the same house with such antecedent cases or in houses next door to them. In more than one-half the instances of next door relationship a child under the age of twelve years was involved either as the antecedent or as the incident case. The disease spread therefore from a preceding case as a center, a phenomenon that could be satisfactorily explained in their opinion only by assuming that pellagra was an infectious disease. Apparently it was not readily transmitted to any considerable distance. In the transmission from family to family the children seemed to play an important part.

Dr. William P. Northrup said that the saying that when the lesion of pellagra encircled the wrist the patient was going to die reminded him of some of the first information he had had about shingles in his student days. It was said at that time that if the shingles went all the way around the body the patient would die; as a matter of fact they never did go all the way around.

Dr. W. T. Longcope said he felt that he had learned more concerning pellagra during the evening than he had ever known before. Dr. MacNeal had put the whole subject in a new and absorbingly interesting light. Before hearing this report it had occurred to him, as probably to many others, that there were many points of close analogy between beriberi and pellagra, but this idea had been entirely dispelled by Dr. MacNeal's presentation. This report left little basis for the old assumption that pellagra was associated with the ingestion of spoiled corn. Dr. Longcope asked Dr. MacNeal whether one would be justified in making the diagnosis of pellagra when skin lesions did not exist, and also whether he had observed the development of pellagra in suckling infants.

Dr. Alvah H. Doty said that he had always believed that pellagra, like beriberi, was due largely to improper food and malnutrition. While malnutrition might not be a factor in the early stage of the disease, he thought it played an important part as the disease advanced.

Dr. William P. Northrup asked what the popular opinions of the people were regarding pellagra. He said it would be most interesting to hear what the prevailing opinions were among the people.

Dr. W. J. MacNeal said he did not know whether he could answer all the questions asked. If he had forgotten any he hoped he would be reminded of them. As to the diagnosis of pellagra without skin lesions, in the work of the Thompson-MacFadden Commission, no cases were accepted as definite pellagrins unless the skin lesions had been observed either by themselves or by a local physician. Skin lesions might be present in a typical form for only a few days in some cases, so their absence did not negative a diagnosis of pellagra. Cases often went for months without skin lesions and one could not exclude pellagra just because the skin lesions had not been seen. The subject of an insect carrier or secondary host of the parasite of pellagra had been carefully studied by Mr. A. H. Jennings and Mr. W. V. King of the Bureau of Entomology, United States Department of Agriculture, working in collaboration with this commission. Dr. Sambon of London had stated that pellagra was contracted chiefly by field workers and he had incriminated the buffalo gnat (*Simulium*) in its transmission. Jennings and King observed that the disease was contracted chiefly by persons remaining in or about the dwelling house in the daytime and they had suggested that the stable fly (*Stomoxys calcitrans*) might play a rôle in its dissemination. The evidence, however, was inconclusive. The methods used for the disposal of sewage seemed to have something to do with the spread of pellagra. In those portions of the city of Spartansburg equipped with a water carriage sewer system

relatively few cases of pellagra developed, while in those parts of the city where surface privies were used there were many more cases of this disease. To get more definite observations on this point an investigation was made of mill villages with sewer systems. Only three such villages were found and in two of these the water carriage sewer system had been in use for only one and three years respectively. In the third village the water carriage sewer system had been in use for twenty years. A number of cases of pellagra had moved into this village from time to time, but no new case could be proven to have originated there. In regard to the treatment of pellagra, no specific was offered, but very good results had been obtained in several cases. The important therapeutic measures included removal of the patient to a cooler climate, or provision for a comfortably cool temperature in his room, careful but full feeding with plenty of milk and eggs, scrupulous cleanliness, efficient nursing, and cheerful optimism on the part of everyone around the patient. Fourteen patients suffering with pellagra, brought to the Post-Graduate Hospital in 1913, were treated along these lines and all of them recovered from the acute manifestations of the disease, although most of them relapsed the following year after returning to their former environment. Observations were made on a number of cases treated in a hospital in the South by different methods of specific treatment, but several deaths occurred. Personally, Dr. MacNeal said he was opposed to the use of arsenic or other supposed specific treatment during the active stage of the acute attack, but this opinion was not shared by other members of the commission. Salvarsan had been used in the treatment of pellagra, but there would seem to be no real justification for its employment. In reply to the question as to whether he had seen any cases of pellagra in suckling children, Dr. MacNeal said that he had not seen any such cases, but some had been reported on reliable authority. Among the cases on the records of the Thompson-MacFadden Pellagra Commission there was none less than one year of age.

---

SECTION ON MEDICINE.

*Stated Meeting, Held February* 17, 1914.

DR. T. STUART HART IN THE CHAIR.

THE contributions were from the medical wards of the Lebanon Hospital.

**Gangrene of the Lung; Operation and Recovery.**—Dr. ABRAHAM MAYER reported this case. The patient was a man thirty-six years of age, born in Italy, and admitted to Lebanon Hospital September 11, 1913. His family history was negative, his father dying of intestinal trouble at the age of sixty and his mother of pneumonia at the age of eighty years. The patient had never before been ill. Twenty-four days before his admission to the hospital he had been suddenly taken sick with a severe chill, followed by high fever. He had severe pain in the right chest with each inspiration. Expectoration, at first slight, became progressively more and more profuse. He was at first thought to have lobar pneumonia, but did not seem to have any crisis. At the time of his admission to the hospital he was only fairly well nourished, looked ill, and had a hot, dry skin. His heart percussed normally as to position and size. The sounds were of good quality and there were no murmurs. The expansion of the lungs was only fair and appeared equal. On the left side there was normal pulmonary resonance, both anteriorly and posteriorly. The respiratory murmur was normal. On the right side posteriorly and just below the angle of the scapula there was an area of dullness, with entire absence of breathing. Radiating from this point as a center moist râles were present over the entire side anteriorly and posteriorly. Examination of the abdomen and the extremities showed no abnormalities. The sputum was very profuse, fetid, and greenish-brown. It contained shreds, and on standing settled into two distinct layers—the lower greenish-red or brown, and thick, the upper more abundant, pale, and thin. When fresh it had a frothy layer which disappeared after standing from twenty-four to thirty hours. Microscopically no tubercle bacilli were found. There were many bacteria, granular and fatty matter, and many crystals. There were few elastic fibers. The first *x*-ray was taken September 15, 1913, and showed a large area on the right side affected. On account of the wretched condition of the patient the operation of opening the chest wall and evacuating the gangrenous material was divided into two stages. The preliminary operation was done on September 19 and on September 22 the operation was completed. Foul-smelling, grumous material and lung detritus were found. The cavity was the size of a lemon and extended to the root of the lung. The patient made a complete and uneventful recovery and was discharged cured thirty-seven days after admission to the hospital. Dr. Mayer exhibited the *x*-ray plates and a specimen of the sputum.

**Traumatic Epilepsy of Five Years' Duration Cured by Surgical Treatment.**—Dr. WILLIAM M. LESZYNSKY presented this report. He stated that experience and observation had shown that surgical operation upon the skull or brain for the cure of epilepsy had well-defined limitations. The indications for operation were epilepsy following cranial traumatism, Jacksonian epilepsy, and grand mal attacks in which there was distinct clinical evidence of a focal lesion. The earlier the operation was performed after the cranial traumatism the more favorable the prognosis. The subject of this report was a man twenty-six years of age, who first consulted Dr. Leszynsky May 18, 1910. When six years of age he had fallen from a height and received a compound fracture of the skull over the vault on the right side. He made an apparent recovery and his physical and mental condition developed normally. He remained in perfect health until the age of twenty-one years, fifteen years after the injury, when he had an attack of clonic spasm affecting the muscles of the left hand and forearm, which was followed by loss of consciousness and a general epileptic convulsion. These attacks had recurred about once a month for the past five years and had not varied in character or intensity. Over the right temporoparietal region there was an irregularly shaped, deep depression (the bone having been removed surgically at the time of the cranial injury) one and one-half inches in diameter, about three and one-half inches above the mastoid process and two inches from the median line. Physical examination revealed nothing otherwise abnormal. It was quite evident that the epileptic attacks were due to focal irritation and early operation was advised. The operation was performed May 23, 1910, by Dr. Henry Roth. There was a scar from a curved incision over the right temporoparietal region, and within this another crucial scar, which was hard, depressed, adherent, and pulsating. The central area showed absence of bone and was about an inch and a half in diameter. The edge of the bone defect was removed. The raised flap consisted of scalp and dura directly over the precentral convolution, including all of the scars. After all bleeding was checked the exposed brain tissue was covered with Cargile membrane, the flap replaced and sutured with silk, a small rubber tissue drain being left in the lower angle of the wound. The patient made a good recovery and had been kept under observation during the following year. He had never had any form of epileptic attack since the date of the operation, a period of three years and seven months. His general health had remained good and he had never received any sedative drugs.

**Gaucher's Disease in a Boy.**—Dr. CHARLES HERRMAN presented the clinical report on this case. The patient was now fourteen years of age. His mother was healthy. His father had had a gastric ulcer for which a gastroenterostomy was performed. There were eight other children. A sister twenty-seven years of age had a tuberculous coxitis and an enlarged spleen. It was noteworthy that these two children were the last of a large family. The patient had had measles and whooping cough, but no manifestations of syphilis, tuberculosis, or malaria at any time. Dr. Herrman said he had first seen the child in 1906 when he was six years of age. The mother said she had observed an enlargement of the abdomen when the child was four years of age. At the age of six and a half years the child had severe abdominal pains and epistaxis. Examination showed a spleen extending eight c.m. below the level of the umbilicus and one c.m. beyond the umbilicus in the median line. The lymph nodes were not distinctly enlarged. The blood showed hemoglobin 75 per cent., red blood corpuscles 4,390,000, white blood corpuscles 4,000, polymorphonuclears 70 per cent., lymphocytes 29 per cent., and eosinophiles 1 per cent. Quinine, arsenic, iron, mercury, and iodides were given at various times without any apparent effect. In January, 1909, the patient had a tooth extracted and this was followed by hemorrhage. In July, 1909, he had severe abdominal pains and vomited a large quantity of blood. He was then admitted to the Lebanon Hospital and remained there one month. The liver extended from the fifth rib above to five c.m. below the

free border of the ribs in the right main line. The spleen extended from the seventh rib above to fifteen c.m. below the free border of the ribs in the axillary line and one and one-half c.m. beyond the umbilicus in the median line. There was some discoloration of the face and a peculiar wedge-shaped thickening of the conjunctiva on either side of the cornea, to which Dr. Brill had called attention. The patient received *x*-ray treatments without any apparent effect. On February 12, 1912, the patient was presented before the Pediatric Section of the New York Academy of Medicine, at which time Dr. Brill made a positive diagnosis of Gaucher's disease. In October, 1913, the patient was again admitted to Lebanon Hospital when he gave a history of having had several hemorrhages from the nose and mouth during the preceding week. He was very pale, had lost in weight, and complained of feeling badly, being troubled with headaches, nausea and dizziness. He was so decidedly worse that it was decided to have a splenectomy performed. Dr. Roth performed this operation on October 22. The patient made a good recovery and was discharged December 11, 1913. He still complained of occasional pain in the abdomen and legs. As a result of the operation there was an increase in the hemoglobin and red blood cells, and a marked increase in the white blood corpuscles, together with an increase in the percentage of polymorphonuclears. It was too early to say that the patient was cured, as the spleen was not the only organ affected, but it did not seem likely that an organ so distinctly changed could be of any value, and it might be that by removing it the organism might be better able to cope with the as yet unknown agent causing this condition.

Dr. HENRY ROTH described the operation performed on this patient whose history had been related by Dr. Herrman. He said that on October 22, 1913, under nitrous oxide gas and ether anesthesia, a vertical incision was made through the outer border of the left rectus muscle, sufficiently long to permit safe manipulation and delivery of the enlarged spleen. Adhesions were present on the upper and posterior surfaces which were readily divided after the vascular pedicle was first secured with a rubber covered clamp, ligated in sections with catgut, and divided between ligatures. The distal one inch of the pancreas was included in one of the ligatures and part of it was removed with the spleen. After covering the raw surface with peritoneum a small cigarette drain was placed down to the stump. The abdominal incision was closed by several layer sutures. The patient stood the operation remarkably well, and was discharged from the hospital forty-nine days after the operation. In an article recently published by N. E. Brill and F. S. Mandlebaum in the *American Journal of Medical Science*, 1913, CXLVI, 863, it was stated that of fourteen authenticated cases of this disease eight had splenectomies performed with five recoveries and three deaths as the result of the operation J. F. Erdmann and J. J. Moorhead (*American Journal of Medical Science*, February, 1914, CXLVII. 213) gave a list of ten operative cases, including two of Wilson's cases, which Mandlebaum did not consider to be types of this disease. The one authenticated case of Gaucher's disease reported by Wilson and operated upon by William J. Mayo on January 7, 1907, died. Erdmann and Moorhead were in error when they counted this case as a recovery. A corrected list showed only eight operative cases, with five recoveries and three deaths. This was the third male case on record and the second male case subjected to splenectomy. He was the sixth patient operated on in this country. In view of the fact that all other forms of treatment had thus far failed to bring about the same amount of improvement which followed splenectomy, the latter procedure seemed justifiable because, even if improvement proved only temporary, splenectomy would surely relieve the symptoms caused by the increased size and weight of the spleen. Furthermore, the improvement in the condition of the blood tended to indicate that the removal of the spleen in this disease had a beneficial effect. Splenectomy was a comparatively safe operation, providing it was done before the general condition of the patient became such that any other procedure of equal magnitude would be too dangerous.

Dr. EUGENE P. BERNSTEIN made the pathological report on the specimen from this patient. He stated that the spleen measured 27 x 13 x 10 cm. in its various dimensions and weighed 1320 grams, or almost three pounds. Its surface was wrinkled and of a translucent purple color. On cut section the capsule was seen to be somewhat thickened. The parenchyma was of reddish-brown color, mottled everywhere with minute hemorrhagic areas about the size of a pin head. The organ cut with considerable resistance, nowhere exuding blood, and presented a firm homogeneous surface from which very little pulp could be scraped off. Malpighian bodies were not distinguishable. The spreads made from the splenic pulp immediately after operation showed numerous large endothelial cells, with irregular outlines, containing one or more fairly large, round, or ovoid shaped nuclei which were rich in chromatin, and were usually situated eccentrically. The number of nuclei in one cell might be very large; in this case the highest count was seven. The protoplasm of the cell was roughly homogeneous. On microscopic section the most prominent feature was the enormous distention of the venous sinuses which were filled with erythrocytes and the above described endothelial cells. The sinuses were round or oval and lined with endothelium. Here and there were found islands of fairly normal pulp cells. The wall of the sinuses was composed of connective tissue supporting the endothelial cells but reticulum fibers were never found extending into the lumen of the aveoli. This was the typical pathological picture of the spleen in this disease which still remained to be explained. The only point of accord among authors was that these cells must arise from the hematopoietic system. Besides being found in the spleen, they were also present in the liver, lymph nodes, and bone marrow.

**Cerebral Syphilis, Treatment with Salvarsan as a Last Resort with Complete Recovery.**—Dr. WILLIAM WEINBERGER presented this patient, a woman thirty-eight years of age, who had been admitted to the medical service of the Lebanon Hospital April 11, 1912, complaining of persistent vomiting, severe headache, dizziness, tingling sensations, and a sense of insecurity in the lower extremities, rendering walking and even sitting difficult. For two or three days she had had difficulty in starting urination. She had had five miscarriages during her married life. Physical examination revealed that the axillary and inguinal lymph nodes were palpable, the pupils unequal, the left being larger than the right, slowly reacting to light; ocular motility was normal; there was occasional nystagmus. The tongue was tremulous, but protruded normally. There was marked pain and tenderness on pressure in both occipital regions with tenderness over the vertebral spines extending down to the middorsal region. There was also tenderness on pressure over the sternum and both tibiæ. The upper extremities were normal, but the lower showed general emaciation. Both knee jerks were slightly exaggerated and there was occasional pseudoclonus on the right side. The plantar reflexes extending down to the mid-dorsal region. There was no objective sensory disturbances. The gait was epistatic and the Romberg marked. Eye ground examination showed residua of a previous specific neuritis. The temperature was normal throughout. The urine contained faint traces of albumin and a few hyaline and occasional granular casts. The Wassermann in the blood was positive. The cerebrospinal fluid was negative, globulin was positive, lymphocytes 30 per cent. This was corroborated by another lumbar puncture. The blood picture examination showed a picture of moderate secondary anemia. On the basis of these findings a diagnosis of basal meningoencephalitis of a specific character extending into the posterior fossa was made. For a number of weeks about ten large doses of iodides, up to 100 minims t.i.d., and injections into the glutei of 20 per cent. mercuric salicylate suspension were given with no amelioration of the symptoms. As a last resort an intravenous injection of 0.6 salvarsan was given. The improvement became manifest about three days after the injection. First the vomiting and headache were favorably influenced, the gait improved, and the nystagmus became less distinct. Another 0.6 gram of salvarsan was then administered as these symptoms persisted. This was followed in the course of time by a complete removal of all symptoms with the exception of a slight degree of nystagmus. When discharged the patient weighed 97¾ pounds as against 73 when admitted to the hospital. The patient was in the hospital for three months and ten days. She had remained well up to the present time.

**Large Aneurysm of the Aorta without Symptoms.**—Dr. SELIAN NEUHOF reported this case. The patient was a man, 67 years of age, who had always been a heavy smoker. His health had been good except for occasional mild attacks of indigestion until 1913, when he began to have slight pains on the left side of his chest and very slight dyspnea when climbing stairs. He gave a history of venereal infection forty years previ-

ous to this time. Outside of his heart and arteries the physical examination was negative. Inspection of the neck showed somewhat exaggerated throbbing carotids. On palpation the thrust at the apex and at the base, both right and left, was somewhat stronger than usual. On percussion the apex was found at the nipple line; apparently the cardiac area was not enlarged. Auscultation showed that at the apex and the lower precordium there was a somewhat rough systolic murmur and a softer murmur replacing the second sound. Both murmurs were transmitted somewhat to the left and towards the sternal border. At the base there was double murmur, the rougher and louder being the systolic. Both were transmitted somewhat above but mainly along the right sternal border. The last examination made a few days ago corroborated all these findings. The average of the blood pressure readings was, systolic 170, diastolic 70. The patient's reflexes were normal. The Wassermann reaction was negative, the Noguchi positive. The examination led one to infer that the patient most probably had a luetic aortitis with aortic dilatation. The orthodiascopic tracing, however, as well as the *x*-ray plates, showed that the patient had a long fusiform aneurysm beginning at about the end of the arch reaching to and probably partly involving the upper abdominal aorta. This latter fact was particularly well seen in the *x*-ray. The patient was given salvarsan intravenously and numerous doses of mercurial injections as well as iodide of potassium. The special points of interest were the long latent period after the infection, the comparative absence of symptoms, with the exception of a few days, the entire absence of decompensation, the absence of all physical signs pointing to a large aneurysm in this location, and the excellent state of preservation of the patient despite his advanced years. This case illustrated the value of the orthodiascope and *x*-ray since without them the diagnosis of this case would have been impossible.

**Typhoid Fever Complicating Malaria.**—Dr. CARL GOLDMARK reported this case. The patient was a girl, 20 years of age, whose family and personal history were absolutely negative. She was admitted to Lebanon Hospital October 10, 1913, with the diagnosis of typhoid fever. One week prior to admission she began to suffer from nausea and vomiting, headaches, abdominal cramps, fever increasing toward evening, and an occasional chill. Her bowels were constipated. These symptoms continued up to the time of admission, at which time her temperature was 100° F., and pulse 112. The physical examination revealed nothing. The Widal and diazo tests were negative. The evening of admission her temperature rose to 105° F. with morning remission to normal. Two days later she had a chill and her temperature rose to 105.5° F. Blood taken durthe chill showed plasmodia of the tertian type. The administration of quinine promptly checked the malaria and for the next nine days the temperature remained practically normal with an occasional rise to 100° F. The patient was discharged as cured twelve days after admission. Nine days later she was readmitted stating that she had felt perfectly well for five days after her discharge from the hospital and that then she started as before with vomiting, abdominal cramps, and fever. Two days before admission she had had a chill, high fever, and perspiration. The physical examination again revealed nothing. There was no roseola. The Widal test was negative. The patient was immediately put on quinine, and for the next two days the temperature varied from 100° to 102° F. As the patient had been taking quinine before admission it was thought that possibly they were dealing with a case of quinine fever and the quinine was discontinued for three days, during which time the evening temperature rose to 104.5° and 106.5° F. with a morning temperature of 101° to 102.5° F. The Wassermann and von Pirquet tests were both negative. Warburg's tincture was administered. The patient then had two chills, one in the morning with a temperature of 106° F., and one in the evening with a temperature of 107° F. The blood was taken during the chills and failed to reveal anything characteristic. The following day the patient had another chill, the temperature going to 106° F. Quinine was given hypodermatically and there was no chill for the next two days though the temperature rose to 105.5° F. Quinine was discontinued and methyl blue tried. During the following two days there were chills with a temperature of 106° F., and during the four following days the temperatures were considerably lowered and unaccompanied by chills. The morning remissions continued. The spleen was somewhat enlarged but otherwise there was nothing that was of assistance in clearing up the diagnosis. They thought they were dealing with a case of malaria complicated by typhoid fever though they had no corroborative evidence upon which to base a positive diagnosis. The patient's temperature again rose to 105° F. and they determined to use neosalvarsan. An intravenous injection was given and the result was striking. The temperature which had been 102.5° F. promptly dropped to 96.5° F. and the whole complexion of the case was changed. Whatever rôle the malarial element was playing to mask the real underlying condition was absolutely eliminated. The typhoid fever now asserted itself and the temperature curve at once became typical of this condition. The Widal test, however, still, remained negative for the next five days when at last a positive Widal reaction was reported on the forty-first day of the patient's first attack or the twenty-first day of the second. The blood culture made by Dr. Bernstein now showed a pure culture of *Bacterium coli communis*. A smear from an abscess that formed at the bend of the elbow also showed the colon bacillus. About a month later another abscess formed on the thigh and this culture showed pure typhoid. The Widal remained positive. The typhoid fever ran a fairly stormy course with a recrudescence on the fifty-seventh day. With the setting in of this rise a slight roseola was apparent for the first time. The patient was discharged from the hospital as cured on the one hundred and tenth day following the appearance of the first symptoms.

## Philadelphia Neurological Society.

At a stated meeting held February 27 in Cadwalader Hall of the College of Physicians, Dr. CHARLES K. MILLS presented a communication entitled "The Different Theories of Aphasia: Can They Be Made to Harmonize?" Dr. F. X. DERCUM discussed "The Clinical Interpretation of Aphasia." Dr. CHARLES W. BURR read a paper entitled "The Relation of Aphasia to Mental Disease." He contended that the dementia often, if not invariably, associated with aphasia is not due to this disorder as such, but is to be attributed to coincident or independent conditions, such as arteriosclerosis, senile degeneration, and the like. Dr. J. HENDRIE LLOYD presented a communication entitled "Sensorimotor Aphasia." Dr. J. H. W. RHEIN read a paper entitled "Apraxia in Relation to Aphasia." Dr. T. H. WEISENBURG read a communication entitled "Anarthria." He protested against the employment of this term to mean inability to speak dependent upon other causes than interference with the function of the organs of phonation and articulation, such as paralysis of lips, tongue, vocal bands, and the like. Inability to speak due to disorders of the central nervous control of the faculty of speech is aphasia. Dr. WM. G. SPILLER exhibited a group of specimens illustrating lesions of the left third frontal convolution and of the temporosphenoidal lobe, in which there were present respectively motor and sensory aphasia. Rarely, however, the speaker said, is the lesion so circumscribed as to be confined exclusively to a single center or to a single localization-area.

**Nervous Cretinism.**—F. G. Crookshank reports the case of a girl, now aged five and a half years, who was in August, 1912, brought to the Belgrave Hospital. The notes then made stated that the child had spoken early, but walked late; that the present complaint was one of slime coming from the mouth, of stumbling, and of being miserable. It was recorded that the skin was harsh, the gait tottery, the knee-jerks increased. A diagnosis of "xerodermia with (?) hypothyroidism" was made, and small doses of thyroid were given. Subsequently, the author saw the child irregularly: little change if any for the better occurred, and the speech became defective. In the spring of 1913, after the demonstration by Langmead of a case of nervous cretinism it occurred to the author that his case was one of the same character. The gait then was more than ataxic; it was that of a child with "ataxic paraplegia." The dose of thyroid was quickly increased and regularly maintained, and the child now walked and talked well, and had lost almost all her symptoms. She was growing fast.—*Proceedings of the Royal Society of Medicine.*

## Books Received.

*The* Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Die Zuckerkrankheit. By Dr. med. A. Sopp. Paper; 90 pages; price 1.80 M. Curt Kabitzsch, Würzburg.

Progressive Medicine. Edited by Hobart Amory Hare, M.D. Assisted by Leighton F. Appleman, M.D. March 1, 1914. Vol. XVI, No. 1. Paper; illustrated; 406 pages; price $6.00 per annum. Lea & Febiger, Philadelphia and New York.

Entstehung und Entwickelung der Laryngoskopie. By Prof. Dr. Emerich von Navratil. Paper; 53 pages; price 1.60 Mk. August Hirschwald, Berlin.

Gelandebehandlung Herzkranker Kinder im Mittelgebirge. By Dr. H. Roeder. Paper; illustrated; 164 pages; price 3.60 Mks. August Hirschwald, Berlin.

## Therapeutic Hints.

**A Lotion for Use in Urticaria.**—Bouchard employs the following:

℞ Cocaine hydrochloride,
Chloral hydrate,
Resorcin, āā, 2 grams.
Glycerin, 6 grams.
Alcohol, 40 grams.
Cherry laurel water, 60 grams.
Distilled water, 90 grams.

**The Application of Horse Serum in the Treatment of Wounds.**—M. H. Roziès points out that horse serum is a valuable antiseptic when locally applied to wounds. It is harmless and may be employed in the case of all wounds whether these are clean or infected. It has analgesic properties which are of distinct service in the treatment of burns. In the case of sluggish wounds horse serum stimulates the reparative processes.—*Gazette des Hôpitaux.*

**The Relief of Gastric Flatulence.**—According to A. P. Luff this may be effected by means of the following mixture:

℞ Aromatic spirit of ammonia, 25 minims.
Spirit of chloroform, 15 minims.
Spirit of peppermint, 12 minims.
Spirit of cajuput (B. P., oil of cajuput 1, alcohol 9), 8 minims.

This constitutes a teaspoonful dose, which is to be taken in a wineglassful of water whenever the flatulence becomes troublesome.—*Lancet.*

**Treatment of Tardy Malnutrition of Syphilitic Origin.**—C. G. Kerley states that he has employed the following prescription in the treatment of this condition in children from five to ten years of age:

℞ Bichloride of mercury, 1/60 grain.
Tincture of nux vomica, 3 drops.
Ferrated extract of apples, 1/3 grain.
Quinine bisulphate, 2 grains.

This should be given in a capsule three times daily after meals.—"Practice of Pediatrics."

**The Relief of Pain.**—A. P. Luff states that when the use of morphine is not desirable a combination of analgesics such as the following may be employed:

℞ Novaspirin, 7 grains.
Pyramidon, 6 grains.
Quinine salicylate, 1½ grains.
Codeine, 1/3 grain.

This is to be prescribed in a cachet to be taken every four hours.

**An Effective Combination in Gout.**—A. P. Luff recommends the following in the treatment of acute and subacute gout:

℞ Colchicine, 1/70 grain.
Sugar of milk, ½ grain.
Extract of nux vomica, ¼ grain.
Extract of hyoscyamus, ½ grain.
Extract of gentian, q. s.

This should be administered in pill form. The object of the sugar of milk is to allow the colchicine to be triturated with it before the colchicine is worked up with the extracts, as otherwise the minute amount of the alkaloid would not be evenly diffused throughout the pill mass, and so the risk of a poisonous dose of colchicine getting into one pill might be incurred. One pill is to be taken every three or four hours according to the severity of the attack, which is rapidly relieved by this treatment.—*Lancet.*

### SYPHILIS IN RELATION TO LIFE INSURANCE.*

By HENRY H. SCHROEDER, M.D.,

NEW YORK.

MEDICAL DIRECTOR, MUTUAL LIFE INSURANCE CO. OF NEW YORK; EDITOR OF THE INSURANCE DEPARTMENT, MEDICAL RECORD.

THE crude practice followed in the past for arriving at the value of a risk with a syphilitic history must be given up sooner or later in favor of a more scientific mode of selection, based on the successful results attained in serum diagnosis and modern therapy. The medical officers of life insurance companies have wisely waited until the results of experimental research could be formulated into some practical system. Needless to say, the limitations as well as the advantages of this improved method will not be recognized without a clear understanding of the principles upon which it is founded. Medical directors lead busy lives, and many of them have little time or opportunity for following up the developments in syphilology in a connected way, the literature from dependable sources being scattered, desultory, and confusing. With these suppositions the writer has ventured to present a general review of the accomplishments in experimental research, the mortality, the results of treatment, the causes of death, and the conclusions which may be drawn in the interests of life insurance.

EXPERIMENTAL RESEARCH.—A connected and sufficiently comprehensible digest of this subject, omitting most details of the complicated technique, is included in the following lines:

*Spirochæta Pallida.*—This microorganism of syphilis in man, otherwise known as *Treponema pallidum*, is long, delicate, and non-refractile, has the appearance of a spirally wound wire, and is highly motile. The *Spirochæta pallida* is one member of a large group. Some forms are harmless, others are pathogenic. The *Spirochæta refringens* is one form which is apt to cause considerable difficulty in microscopic identification, as it occurs on ulcerating lesions, in smegma, and on venereal warts; in other words, it is likely to be found just where the *Spirochæta pallida* is sought.

*The Demonstration of Spirochæta Pallida.*—The *Spirochæta pallida* may be detected, in most cases, by microscopical examination in the primary stage of syphilis. This method will probably be more generally adopted in the future, as the Wassermann reaction is of little value before the spirochetes have entered the circulation. It will then be practicable to secure a statement of real value in regard to the nature of the acknowledged venereal sore when the patient becomes an applicant for insurance later on. Every one interested in life insurance medicine has had the task of puzzling over conflicting or doubtful statements in regard to some lesion admitted in the personal history, and of trying to determine whether it was chancre, chancroid, herpes, or some unimportant sore. Another advantage gained from employing this method is the opportunity to make an early diagnosis without waiting, as formerly, for the appearance of the secondaries to gain definite knowledge of the nature of the disease before beginning treatment.

The serum for examination is extracted from the sore. The dark illumination field probably affords the most practicable means for discovering the microorganism, if resorted to before the application of antiseptics or caustics. Rapidity in reaching a result is the great advantage of this method. The other methods are based upon the use of stains. A negative result after one attempt does not justify the exclusion of syphilis any more than the failure to find the tubercle bacillus in one sample proves that the patient is non-tuberculous. Experience, great care, and persistence are required in finding the specific germ of syphilis, and differentiating it from other microorganisms.

*The Luetin Test.*—Noguchi, who perfected this method, uses a suspension of pure cultures of killed spirochetes under the name of "luetin" for the purpose of making a cutaneous test for syphilis. The preparation is injected intradermically in one arm, and a control is often employed on the other. It usually takes from five to six days, sometimes considerably longer, for a positive reaction to appear in the form of a red papule with an area of induration. The papule may go on to pustulation or may persist for some weeks after treatment and after the Wassermann reaction becomes negative. The process is direct and specific, like the tuberculin test, and is particularly helpful in the diagnosis of latent and tertiary cases.

According to Noguchi, the reaction is present in the majority of cases of tertiary, latent, and hereditary syphilis. In general paresis and tabes a positive reaction is obtained in about 60 per cent. of cases. In certain cases of tertiary and hereditary syphilis an inflammatory reaction occurs at the site of the injection of the control fluid, and this may be as strong as that produced at the site of the luetin inoculation.

Nichols reports positive reactions in 87.5 per cent. in latent cases, the ordinary Wassermann indicating only 25 per cent. In latent and tertiary cases together, there were positive results in 84 per cent. against 53 per cent. with the ordinary Wassermann. Five cases are cited in which ordinary Wassermann reactions had been obtained during periods ranging from 15 to 22 months, but in

*Read at meeting of the Medical Section of the American Life Convention, March 5, 1914.

which the application of the luetin test gave indication that syphilis was still present. The use of this method has been greatly restricted through the impossibility of securing good luetin. Noguchi makes the only reliable preparation in his private laboratory, and the supply is therefore very limited. Moreover, the method will not come into general use until it is well known and accepted that there is no risk involved in submitting to the inoculation.

*Complement Deviation or Fixation Test.*—The chemical action in this phenomenon has not been satisfactorily explained. The following terms appear frequently, and require some explanation:

1. Complement is a substance found in the sera of all animals. When joined by an antibody (also known as amboceptor) it dissolves bacteria and red blood cells, but has no power to accomplish this when the amboceptor is absent. Complement is thermolabile, being destroyed by a heat of 55° C. The serum is said to be "inactivated" when the complement has been destroyed by heat. Such a serum may be "reactivated" by the addition of other free complement. Complement has little specificity, so that the complement of the serum of one animal is capable of reactivating the sera of other animals. The blood of the guinea-pig supplies complement which has most ability to reactivate the sera of other animals, and is more uniform in strength.

2. The amboceptor or antibody is formed in the fluids of an animal, accidentally by disease, or intentionally (causing immunity) by the injection of a special cell or poison (antigen). The amboceptors entering into the complement fixation reaction for the detection of syphilis, to be referred to later, are:

A. The amboceptor formed in the blood of the patient by syphilis.

B. The amboceptor formed in the rabbit by the injection of sheep cells.

Amboceptor is highly specific; for instance, the amboceptor of immunized typhoid blood will not unite with complement and destroy sheep cells or the bacilli of any other disease. It is thermostabile, not being destroyed by a heat of 55° C. Serum can, therefore, be inactivated by destruction of the complement by a heat of 55° C. and still have the amboceptor unaffected.

3. Antigen is a body capable of stimulating the formation of antibodies or amboceptor, thereby establishing so-called "immunity." All bacteria, red blood cells and certain other substances are antigens.

When an antigen is present with the amboceptor for whose formation the former is responsible, the amboceptor will attract complement and cause hemolysis.

4. Taking a step backward and reviewing the evolution of the reaction, it may be gathered from the literature that Bordet and Gengou discovered as early as 1901 that if pure cultures of the spirillum of Asiatic cholera were injected into rabbits, immunity was established to the spirillum in these rabbits. Furthermore, if pure cultures of the spirillum were added to the serum of the immunized rabbits, the spirilla were dissolved or destroyed. If, however, the cultures were put in the serum of untreated rabbits, the spirilla were not affected. In attempting to ascertain what substances in the immunized blood were responsible for this destruction or "lysis," it was found that if immunized blood was heated to 55° C. for an hour, it would no longer dissolve the bacteria. Further experiments revealed the fact that if some normal serum was added to the immune serum that had been inactivated by heat, its bacteriolytic power was restored. In this way immunized blood was found to contain two substances which caused dissolution of bacteria, the thermolabile substance now known as complement, and the thermostable substance now known as amboceptor. Later, it was learned that if washed red corpuscles of an animal were injected subcutaneously into an animal of a different species, the latter would become immune to those red cells. For instance, if washed red cells of a sheep were injected into a rabbit, the rabbit became immunized to sheep red cells, and if the serum of the rabbit were separated and mixed with sheep cells, the latter would become dissolved by the process known as hemolysis, this process depending upon the binding of the amboceptor to the complement by means of the antigen.

The hemolytic system is utilized in the complement fixation reaction as an indicator to show whether complement was bound or remains free after it has taken part in another combination.

If the previous combination included an amboceptor and its particular antigen, complement will be bound to them and rendered unavailable to fill the gap in an incomplete hemolytic system forming the second combination. It will be noticed later that red blood cells are not present in the first combination so as to interfere with the binding of the complement.

The "fixation" or "deviation" of the complement in a serum is accomplished, then, by an antigen-antibody combination, whereby the complement is "bound" and rendered unavailable to complete a reaction in a second antigen-antibody combination for which complement is necessary.

5. Hemolysis, or the dissolution of the red blood cells, is accomplished by the addition of complement and amboceptor. Without the presence of complement hemolysis will not occur. The amboceptor and the cells may combine, however, in the absence of complement, and when so combined the cells are said to be "sensitized." The addition of complement to sensitized red cells results in hemolysis.

The complement fixation reaction in syphilis depends upon the ability of the syphilitic serum to fix complement in the presence of antigen. Individuals with syphilis in any form have syphilitic antibodies or amboceptor in their serum.

A further explanation with the assistance of a schematic drawing will clear up the nature of the reaction.

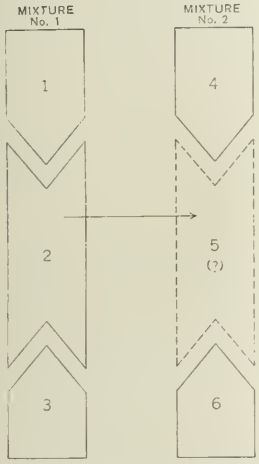
Mixture Number One.—(1) Antigen (extract of syphilitic liver of a fetus) representing the suspected cause of infection. (2) Complement supplied in fresh serum from the guinea-pig. (3) Amboceptor in inactivated serum of the patient. The complement in the serum of the patient must be inactivated by heat. Otherwise, with the introduced known quantity of complement of the guinea-pig, there would be more than sufficient complement to bind (1) antigen and (3) amboceptor, in which case some might pass over to the second antigen-antibody combination and cause hemolysis of the red sheep cells, thereby giving a false impression.

The substances 1, 2, and 3 are incubated a half hour at 37° C. before being added to mixture number two.

Mixture Number Two (another antigen-antibody combination).—(4) Antigen, a fixed quantity of fresh washed sheep cells. These blood cells, the only ones introduced in the test, are depended upon to show whether hemolysis will take place or not. (5) Questionable. This space will not be taken unless the complement of the guinea-pig in mixture number one has not been previously bound and is free to pass over to the second antigen-antibody combination, in which case hemolysis of the red sheep cells occurs and the reaction is then negative. (6) Amboceptor to sheep cells. This is obtained in form of rabbits' serum which has been rendered immune by the injection of red blood cells of a sheep. The rabbits' serum is not always inactivated as the complement in the small amount of serum used is not sufficient to affect the test.

The second mixture is incubated a half hour and added to mixture No. 1.

If the suspected serum is syphilitic, there is an antibody present which has been developed against that particular antigen; the complement will be deviated and hemolysis will be inhibited. In other



words, 1, 2, 3 combine leaving the sheep cells intact and the mixture will remain turbid.

If the patient is not syphilitic no such antibody (amboceptor) is present in his serum. In this event the complement will remain free and hemolysis of the sheep cells will occur. In other words, 1, 2, 3 do not combine, but 2 passes over to 5 and combines with 4 and 6. The sheep cells are then destroyed and hemolysis takes place, giving a negative reaction.

*Titration and Standardization.*—It has been intimated that the complement must be limited to the known quantity and strength contained in the introduced serum of the guinea-pig. This brings up the question of titration, the process for determining the exact strength of the reagents, of the antigen and amboceptor as well as the complement. Serologists should universally adhere to one standard of quantity and strength of the reagents, as their findings will then agree more often and will be correspondingly more valuable. The process of titration and the technique of the tests are delicate, complicated, and tedious, and should be entrusted only to those who have the equipment, experience, ability, and time to carry out every detail with infinite care.

The reagents should be invariably titrated on the day the test is made. The smallest quantity of amboceptor in the presence of which a fixed quantity of red cells will be dissolved by an excess of complement is known as an amboceptor unit. The smallest quantity of complement which in the presence of one amboceptor unit is able to cause solution of the same quantity of red cells is known as a unit of complement. If some other amboceptor with its antigen is mixed with one unit of complement, and time allowed for their combination, the complement will be firmly fixed in that immune system, so that when red cells and one unit of red cell amboceptor are added later, there is no free complement and fixation or deviation of the complement is said to have taken place. The smallest amount of antigen which will completely fix one unit of complement so as to completely inhibit hemolysis in the hemolytic system is known as one unit of antigen.

*Methods.*—The best known applications of this principle are the Wassermann and Noguchi methods. They seem to be equally reliable. Some serologists employ a method composed of what they consider the best features of both tests. Other operators use both tests in every case as a routine measure, finding, when doing so, that the results are sometimes contradictory, and in such an event they accept the positive reaction as an indication of the presence of syphilis.

*Wassermann Test.*—This method is practically the same as that already described in explaining the complement fixation reaction. Since the original investigations by Wassermann, it has been discovered that the hearts of guinea-pigs, oxen, and livers of other animals in alcoholic solution possess the same inhibitory power as the extract of syphilitic livers. These reagents are known as the "organ extract antigens."

*Noguchi's Modification.*—Noguchi recommends a modification of the Wassermann method, claiming that it is more delicate, requires less time and labor, and demands only about one-tenth as much blood from the suspected individual. The great difference between this and the Wassermann method lies in the use of the serum of the rabbit that has been injected with human corpuscles. He found that human serum sometimes contains natural sheep amboceptor, and what would be a positive reaction becomes negative through the presence of this condition.

*Complement Fixation with Spirochæta Culture Antigens.*—Since the success of Noguchi in isolating the *Spirochæta pallida* some operators have substituted a preparation of this microorganism for the organ extract antigen with the hope that the *specific* antigen prepared from such cultures would greatly enhance the value of the complement fixation reaction and eliminate the positive reaction occasionally observed in other diseases. This method has not been in use long enough to justify any conclusions.

*Provocative Wassermann Test.*—Neisser stated before the 17th International Congress of Medicine in London in Sept., 1913, that no opinion concerning a cure for syphilis should ever be expressed until at least a provocative Wassermann test has been resorted to. It is known that some patients who have given a negative Wassermann reaction for over a year, sometimes many years, and in whom

no symptoms appeared during that time, will be found to be still suffering from latent syphilis by means of this test. The method consists of an intravenous injection of salvarsan or neosalvarsan followed by the regular Wassermann test in from 24 to 48 hours, again in about 7 days, and once more in about 14 days. When circumstances permit only one ordinary Wassermann after the injection of the salvarsan, the most reliable result will be obtained by applying the test 3 days after the injection in early cases and 5 days in late cases.

Craig reports a group of 8 cases in which the ordinary Wassermann had been negative for from 15 to 24 months, and were supposed cured. In 4 of the cases, however, the provocative Wassermann proved to be positive. Nichols presents a list of 10 cases with negative ordinary Wassermann for from 15 to 24 months, and were thought to be cured. The provocative Wassermann was positive in 5 of the cases, and the ordinary Wassermann became positive in one of the cases after a period of 24 months.

Craig and Nichols believe that the provocative test in conjunction with the luetin test offers the most available evidence regarding the cure of syphilis. These observers are not prepared to give definite conclusions as to the relative values of the luetin and provocative Wassermann tests, though the provocative Wassermann has given most satisfaction up to the time of their report.

*Interpretation of the Reaction.*—The conventional signs for recording the results of the complement fixation reaction are + +, +, + —, and —. Double plus (++) indicates absolute inhibition; plus (+) indicates at least 50 per cent. of inhibition; plus-minus (+ —) stands for any degree below 50 per cent.; and minus (—) means absolute lack of inhibition of hemolysis. Some serologists employ a slightly modified system for recording their results.

Patients have been assured that they were cured of syphilis upon the strength of a single negative reaction. On the other hand, a diagnosis of syphilis has not infrequently been made in the presence of a plus-minus or a plus reaction, notwithstanding the absence of any history or indication of the disease.

Craig and Nichols are governed by the following conclusions in the interpretation of the reactions, based upon their large experience: If the diseases in which the complement fixation reaction has occasionally been found positive, can be excluded, a double plus reaction is sufficient to establish a diagnosis of syphilis, whether symptoms of the disease are present or not, and whether there is a history of an initial lesion or not.

A plus reaction may be considered as sufficient evidence of the presence of syphilis when there is a history of infection or a presence of clinical symptoms.

A diagnosis should never be made on the appearance of a plus-minus reaction alone. Many normal individuals will give a plus-minus reaction at times, and it cannot be considered, therefore, as having more value than a negative reaction in the absence of a history or symptoms.

A single negative reaction is of no value in excluding syphilis unless repeated tests during the period of a year after the cessation of treatment are all found negative, and a luetin or provocative Wassermann at the end of the year corroborates the negative findings. The examination of the spinal fluid should also be made when possible. In the interpretation of a negative history of the patient, the presence or absence of symptoms and the amount of previous specific treatment must be carefully considered.

The interpretation of the results of the complement fixation test must always rest with the clinician, as the laboratory simply reports the result of the test. It remains, therefore, with the clinician to correlate the laboratory report with the clinical condition or history, and this is only possible when clinicians and the medical officers of life insurance companies, also, have a clear conception of the limitations of the complement fixation reaction in the various stages of syphilis.

It must be added that, in considering the value of the complement fixation reaction, the fact should be borne in mind that laboratory diagnosis is not always the most reliable on account of two factors: 1. The personal equation, or the varying interpretation of the results by different observers. 2. Faulty technique and disregard of standardization.

1. There is a number of degrees between a strong positive and a negative, and the individual opinion of the operator in regard to the exact degree does not always coincide with that of others. Wolbarst analyzes the findings of 37 cases, in which the sera were examined by three competent serologists; agreement occurred in 26 cases, absolute contradiction in 5, and slight discrepancies in 6. It is probable that the discrepancies were due to lack of proper standardization of the reagents.

2. The other factor in the breeding of errors is the failure to resort to careful titration of the reagents.

*Utilization of the Complement Fixation Reaction.*—The reaction is of great value as a guide to treatment either with salvarsan or mercury, an efficient control being furnished for the proper administration of curative agents and detection of relapses by frequent repetitions of the test. Craig and Nichols have demonstrated by means of the complement fixation reaction that there were relapses in 86.8 per cent. of the cases treated by them with salvarsan, most of the relapses occurring within the first 6 months. It would be as difficult to sail a ship without a rudder as to attempt to intelligently treat a patient with syphilis without the assistance of this valuable aid.

The results of the tests will vary within wide limits, becoming negative in about four or five weeks on the average. Cases are reported in which a negative test was secured in six days after the injection of salvarsan, while in others the negative result was not found until 102 days.

The ordinary complement fixation reaction should not be depended upon in establishing a negative diagnosis or in pronouncing a cure. Craig and Nichols, who have contributed largely to this subject through their splendid work, secured the following results:

Starting with the first week after appearance of the initial lesion, they secured 27 per cent. positive and increasing to 79.4 per cent. in the fifth week.

In the secondary stage, Craig examined 1443 cases with active secondary symptoms, of which 95.6 per cent. gave positive reactions. In this stage the complement fixation reaction gives its most reliable results.

In the active tertiary stage the reaction was positive in from 70 to 80 per cent. In latent syphilis 40 to 60 per cent. In congenital syphilis, 90 to 100

per cent. In cerebrospinal syphilis, 40 to 60 per cent.

It is evident, then, that the ordinary complement fixation reaction is a too unreliable and misleading test upon which to base a final decision, especially in late cases, and that the question of a cure can only be solved by a resort to the luetin test, provocative Wassermann test, and examination of the cerebrospinal fluid.

*Precautions, Errors, and Discrepancies.*—Strict asepis should be observed in collecting blood, especially when it may not be examined within twenty-four hours. Fresh blood should be used whenever possible. Craig and Nichols have demonstrated to their satisfaction that certain serum anticomplementary bodies develop under certain circumstances which may give rise to a positive Wassermann reaction.

Aging of the antigen is capable of producing inhibition of hemolysis in doses smaller than ascertained in the original gauging and should be titrated on the day of the test. Old sheep cells develop anticomplementary powers.

A negative Wassermann during a course of treatment with mercurials is of questionable value. At least one month should elapse after leaving off mercury before a negative may be considered significant.

No dependence can be placed on a negative Wassermann in an individual who has ingested a considerable or even fair amount of alcohol within twenty-four hours.

The occurrence of positive tests in such diseases as yaws, malaria, leprosy, and scarlatina does not materially discount the value of the test for syphilis. Most of these affections are exotic. The reaction in scarlatina is transitory and not constantly present. In malarious sections there may be difficulty at times.

Positive reactions in non-syphilitic cases are probably often misinterpretations of negative results due to inexperience, faulty technique, or the failure to follow a recognized standard.

The great and never-to-be-forgotten lesson for every one interested in this line of work is that the tests should invariably be conducted by unquestionably competent serologists, and that the results are unreliable if obtained from other sources. Great practical value of the tests will only be secured by the establishment of central serodiagnostic stations under the control of the health departments and clinics of our large cities.

*The Detection of the Spirochæta Pallida in the Nervous Centers.*—It is recognized that the *Spirochæta pallida* is present in the cerebrospinal fluid in parasyphilis of the nervous centers, the most common of which are general paralysis, tabes, and cerebral syphilis. These diseases are further characterized by an increase in the number of cells and by an increase in globulin.

Neisser, Ellis, and Swift and other serologists are authorities for the statement that the spirochetes colonize in strongholds of poor vascularization in which the nervous system is particularly rich, and where it is difficult for destroying agents to reach them. The perivascular and perineural spaces, as well as the arachnoid space, afford particularly favorite resting places of this kind, and it has been found that there is very little passage of drugs from the blood into these spaces and into the cerebrospinal fluid. Spirochetes lurking in these inaccessible parts and spaces are, therefore, usually beyond the reach of the ordinary or provocative Wassermann test. It has not been demonstrated that the luetin test is reliable enough to justify the final declaration of a cure in these cases.

Ellis and Swift have lately done a lumbar puncture on every patient admitted to the Hospital of the Rockefeller Institute of Medical Research as part of the routine examination irrespective of whether the nervous system showed signs of infection or not. This procedure is justified by them on the principle that if possible abnormalities in the second stage are detected in the beginning, treatment may be started at a time when these abnormal constituents may be made to disappear much more rapidly than later on.

Before, then, the last word can be pronounced as to whether a patient is cured and that there is no latent or tertiary syphilis of the cardiovascular or nervous systems, the following four points of diagnosis, as advised by Nonne, must be cleared up:

1. A provocative Wassermann reaction of the blood.
2. A Wassermann reaction of the spinal fluid carried out according to the method introduced by Hauptman and Hossle in which the quantity of spinal fluid used is about five times greater than the amount of serum taken in the blood test.
3. A cell count of the spinal fluid.
4. A determination of the amount of globulin in the spinal fluid.

Lange's colloidal gold test may be employed in addition to these four methods.

This formidable procedure cannot be requested of applicants applying for insurance unless they happen to be sufficiently desirous of ascertaining for themselves that the disease has been eradicated. The companies will, therefore, sometimes grant policies to applicants who are syphilitic, since the tests which they can call for are limited by feasibility.

Mortality, Treatment and Causes of Death.—A study of the mortality, treatment and causes of death reveals the significance of the results of experimental research.

*Mortality.*—Statistics of the mortality in syphilis are few and unsatisfactory on account of the difficulty, almost impossibility, in tracing the cases. One of the few reports was presented by Dr. Gollmer at the Fourth International Congress of Examining Physicians relating the experience of the Gotha Insurance Company of Germany, between the years 1852 and 1904 in the case of 1,778 men who had been treated for syphilis. There were 487 actual deaths against 290 expected according to the experience of the Gotha among all insured men, a ratio of 168 per cent. An analysis of the statistics according to attained age show the mortality ratio at ages 15 to 35 was 138 per cent.; at ages 36 to 50, 186 per cent.; at ages 51 to 70, 161 per cent.; at ages over 70, 140 per cent. For all ages combined, the mortality ratio for the first five years was 144 per cent., and for the succeeding years, 172 per cent.

Dr. Kaufman Wolf traced the fate of 19 women 20 years after they had been observed by Fleiner in the Heidelberg Clinic in 1891. These women were affected with syphilis in the tertiary stage and were without any history of primary or secondary symptoms. Most of the women were married at the time or married later. Five of the women had died, the cause of death being syphilitic tracheitis, "dropsy," syphilitic cerebrospinal meningitis, pneumonia, and tabes dorsalis. Ten of the

husbands had died, the cause of death being apoplexy in three cases, pneumonia in two, cardio-renal disease in one, tabes dorsalis in one, "dropsy" in one, and accident in remaining two.

The Medico-Actuarial Mortality Investigation has recently completed a study of the experience of the companies represented, the expected deaths being calculated by the Medico-Actuarial table based on standard lives during the years 1885 to 1908 inclusive. The cases are divided into three groups and only include those in which the attack occurred at least three years prior to the date of the application except group No. 3.

1. SYPHILIS, SURELY, THOROUGHLY TREATED, TWO YEARS' CONTINUOUS TREATMENT, AND ONE YEAR FREEDOM FROM SYMPTOMS

| | Actual Deaths | Expected Deaths | Ratio of Actual to Expected Deaths, Per Cent |
|---|---|---|---|
| Between two and five years of application | 13 | 9.32 | 139 |
| Between five and ten years of application | 34 | 19.56 | 174 |
| More than ten years prior to application | 53 | 24.42 | 217 |
| | 100 | 53.30 | 188 |

2. SYPHILIS SURELY, NOT THOROUGHLY TREATED, OR NO DETAILS OF TREATMENT GIVEN

| | Actual Deaths | Expected Deaths | Ratio of Actual to Expected Deaths, Per Cent |
|---|---|---|---|
| Between two and five years of application | 44 | 15.52 | 284 |
| Between five and ten years of application | 54 | 25.52 | 212 |
| More than ten years prior to application | 76 | 59.09 | 129 |
| | 174 | 100.13 | 174 |

3. SYPHILIS, DOUBTFUL

| | Actual Deaths | Expected Deaths | Ratio of Actual to Expected Deaths, Per Cent |
|---|---|---|---|
| More than two years prior to application | 67 | 48.81 | 137 |

Group 1 shows an increasing risk and evidence of the poor results of former modes of treatment, medication having probably been discontinued too soon after the early signs had disappeared, the attending physicians guessing that the cure was complete. The heavy mortality in the late years shows that spirochetes were left lurking in inaccessible parts untouched by treatment.

Group 2 brings out an interesting situation. The mortality was most excessive in the early years, and gradually declined to a still excessive death rate in the late years. The figures seem to corroborate the view held by Keyes and some of his contemporaries that the severe types of syphilis are accompanied by havoc and a comparatively early loss of life, but that after the outburst is well over, the malady appears to more or less exhaust itself so that the surviving patients are less apt to suffer seriously in later life than some of those who have very simple lesions in the early part of the malady. The lighter mortality in the later years in this group appears to have been a case of the "survival of the fittest."

Group 3 shows a mortality more than high enough to prove the necessity of serum diagnosis and proper treatment in doubtful cases.

The Specialized Investigation published in 1903 by the Actuarial Society substantially confirms the conclusions of the Medico-Actuarial Investigating Committee.

*Treatment.*—A general knowledge of the approved and complete method of treatment and the results which may be expected must be in the possession of medical directors before they can successfully cope with the vexed question of whether or not the disease has been eradicated. Statements will be forthcoming from regular physicians testifying to marvelous results from, perhaps, a single dose of salvarsan, the cure having been claimed on the strength of a negative reaction by the simple Wassermann test. Furthermore, another door to charlatanism and quackery has been opened by the introduction of modern chemotherapy and serum diagnosis, both of which afford excellent mediums for deluding the public.

*Salvarsan.*—Ehrlich succeeded in producing this salt of arsenobenzol in experiment number 606, and neosalvarsan, a weaker but less irritating brother, in experiment 914. Neosalvarsan has the advantage of easy solubility and is therefore better adapted for intramuscular injections. The water used must be sterile and chemically pure so as to prevent poisonous bacterial and chemical admixtures of either drug in solution.

*Methods of Treatment.*—Neisser, enlarging upon his own experience, affirmed his belief that mercury and salvarsan destroy the spirochetes, probably, in a direct manner, and also prevent development and multiplication. He believes that salvarsan is far superior to mercury as a means to destroy spirochetes, that it acts more quickly and more intensely, but that a combined salvarsan-mercury treatment is more effective than when either drug is used alone, and, furthermore, that one is enabled in this way to limit the dose of both drugs to a smaller amount, thereby escaping the unpleasant or deleterious effects which are occasionally encountered.

During the first month of the disease, much virus circulates in the blood and it is just at that time that the curative effect of salvarsan is more striking. The fact that unaffected nests of the total mass of spirochetes remain after treatment at times proves that the dosage of the remedy employed was too small, or that the specific microorganism succeeded in reaching centers in the early stages where the remedies could not penetrate. Cases are seen which have been treated in vain for months or years and yet yield finally to appropriate energetic, and careful treatment. It may be regarded a grave error in practice to put off treatment until a typically hard chancre or secondary symptoms develop. The salvarsan treatment should be started as soon as possible after the infection even if the diagnosis is doubtful.

A point of special interest to life insurance companies is that an insufficient total dose during a given period of treatment may result in a "near" cure, thereby eventually doing more harm than good. The danger of "near" cures lies in the fact that when a spirochete center, left latent in the body, again begins to multiply, tissues and fluids that have become normal and bereft of their antispirochetic properties are attacked, and thus in the event of greater proliferation, more damage is done locally than in a tissue still vitiated with syphilis and having more power of resistance. If such a latent spirochete focus becomes reactivated and happens to be lodged in the meninges, some nerve center, or perhaps in or around nerves that branch into a narrow bone canal, the flaring up of the syphilis process may cause serious disturbances.

Neisser holds that the number of relapses in cases well treated with combined salvarsan and

mercury is smaller by far than the proportion of those treated by mercury alone. Unfortunately this rapid beneficial salvarsan effect often misleads patients into prematurely considering themselves cured and to discontinue further treatment. While Neisser is willing to believe that an occasional patient is cured by a single injection of salvarsan if the treatment is begun early enough, he deems it highly important and necessary never to hope for such a result but to let a second treatment follow the first at five or six weeks before a relapse has a chance to develop. He repeats the treatment as often as it is indicated, depending upon the blood reactions for control.

Neisser's experience does not support the assumption that neurorelapses are more common with the salvarsan treatment. He believes that the responsibility for these relapses rests upon the omission of mercury treatment, upon the employment of salvarsan without proper regard to the single or total dosage, upon errors in technique, etc. He deems it especially important for the spinal fluid to be tested in every case before the patient is discharged cured and regrets that this method has not been adopted whenever circumstances permit.

In dealing with syphilis of the central nervous system, it has been found that the direct injection of salvarsan or neosalvarsan into the spinal fluid gives rise to excessive irritation. The blood serum of patients treated with salvarsan has been shown, however, to have a definite therapeutic value when injected into the subarochnoid space. The serum may be taken from another patient or from the patient himself, and must be drawn off within an hour after an intravenous injection of salvarsan. The serum is then inactivated and a culture taken to preclude the presence of microorganisms which might set up a meningitis.

*Causes of Death.*—No disease is so protean in its form as syphilis. Once acquired, it may stamp its impress upon any or all tissues of the body and, even in these days, it is impossible to learn with certainty in some cases when the last imprint of the malady has been stamped out. Lesions of the cardiovascular and nervous systems may, however, be regarded as the chief factors leading to fatal termination.

*Disease of Cardiovascular System.* — Donati pointed out as early as 1909 that syphilis, as an etiological factor, could be demonstrated in 85 per cent. of cases of aortic insufficiency, aneurysm, and mesaortitis, which are suspected from clinical indications. Babcock has emphasized the importance of syphilis in mesaortitis, aortic regurgitation, and aortic aneurysm. In 16 cases of aortic regurgitation observed by him, 15 of the 16 could be attributed to syphilis. Babcock also reported on 10 cases of aortic aneurysm, of which 5 gave positive Wassermann reactions, 2 admitted syphilis, 2 gave no history and were not submitted to a Wassermann, and one gave no Wassermann reaction. In the discussion of Dr. Babcock's paper, Dr. Daland laid particular stress on the predisposition of the spirochetes to endanger the blood vessels even more than the heart itself. Dr. Stone found spirochetes in all cases of aortic disease beginning in the vessels and extending into the heart and it had become a maxim with him to regard all cases beginning after 40 years of age as syphilitic. These reports are corroborated by other competent observers.

Medical directors and examiners are often impressed by the discovery of hardened or thickened arteries in applicants at or considerably under middle age; also by the frequent deaths from cerebral hemorrhage well under the age at which this accident is expected. In most of them, the cause has been imputed to syphilis and, probably, quite justifiably so, as the perivascular spaces are favorite resting centers of the spirochetes. Prompt, energetic, and complete treatment at the right time could have averted the trouble in a large proportion of these cases.

*Disease of the Nervous System.*—Repeated demonstrations of spirochetes in the cerebrospinal fluid in the so-called parasyphilitic diseases give indisputable evidence of the vulnerability of the great nerve centers. Diseases of the brain or spinal cord, as well as of the circulatory apparatus, is a subject of utmost importance to life insurance companies, and while so many of them are known to be of syphilitic origin, the difficulty in excluding them is, nevertheless, greatly increased by the fact that it is impracticable to demand an examination of the spinal fluid for proof that these parts were not invaded during an attack of syphilis which the applicant believes was eradicated. This difficulty, it is hoped, will be lessened at some time in the future by educating the laity, as well as many members of the medical profession, in regard to the vital importance of learning whether the cure is complete or not; further, that a decided opinion is justified only through the knowledge secured by means of the lumbar puncture; and still further, that the process is simple and safe when conducted by competent persons and under proper conditions, both of which may be found at stations equipped for such work.

The responsibility of the specific germ of syphilis in the etiology of many nervous diseases has been satisfactorily demonstrated particularly in cerebral syphilis, general paralysis, and tabes dorsalis. Swift and Ellis give a detailed report of 10 cases of tabes. Spirochetes were discovered in each case, and even when it was not possible to completely exterminate them by means of intraspinous injections of serum taken from the blood of the patient himself or some other syphilitic a few hours after the intraspinous injection of salvarsan, the progress of the disease was more or less arrested. The same observers quote various authorities and give the result of their own experience to show that even in the secondary stage of syphilis, abnormalities of the spinal fluid are indicated at times by an increase in the number of cells, in the amount of globulin, by higher pressure, and by a positive Wassermann reaction of the cerebrospinal fluid. A table of 30 cases exhibited by them divulge the trifling character of the secondary manifestation of syphilis in the majority of patients subsequently developing tabes. Ellis and others hold that syphilitic meningitis may occur in the secondary stage, remain latent, and give no obtrusive symptoms over long periods, and that this complication occurs more frequently than is commonly realized.

Nonne is responsible for the statement that in general paralysis the Wassermann reaction is positive in the blood in almost 100 per cent. and full 100 per cent. in the spinal fluid; in tabes, the reaction is positive in the blood in 60 to 70 per cent., and 100 per cent. in the fluid; in cerebrospinal lues the blood reaction is positive in 80 to 90 per cent. of cases and always positive in the spinal fluid.

Newlin gives an interesting analysis of 43 cases

on all of which the Wassermann and Noguchi methods were employed with positive reactions, the examinations having been carried out by an acknowledged expert. One of the cases was marked as incipient pulmonary tuberculosis (?); tinnitus aurium, 1 case; Henoch's purpura, 1; epilepsy, 14; neurasthenia, 4; hyperthyroidism, 1; hysteria, 1; headache, 1; nephritis, 1; neuritis, 1; sciatica, 1; arteriosclerosis at 50 years of age, 1; one case with intestinal pains and cramps in muscles; Pott's disease, 1; habit spasm, 1; birth palsy, 1; mentally defective and retarded development, 5; congenital lues, 1; Little's disease, 2; chorea, 2; atrophy of scapular muscles, 1.

These few remarks on the rôle taken by syphilis in the causation of disease and death are sufficient to emphasize the ubiquity of the luetic infection and its protean manifestations, it being understood always that syphilis may occasionally be an accompaniment of the disorder rather than the cause.

Conclusions.—Before life insurance companies, as well as the general public, can reap the full benefit of advanced serology and treatment for syphilis, a campaign must be instituted toward overcoming the indifference and ignorance of the laity and educating the members of all grades of society to realize that syphilis may no longer be regarded as a scourge if those affected accept the assistance held out to them and carry out faithfully certain measures which are recognized as of indisputable and inestimable value.

The conclusions directly affecting the interests of life insurance may be arranged as follows:

(1) The medical officers of life insurance companies should not accept an applicant with a syphilitic history until at least one year has elapsed since the date of last treatment, several negative Wassermann's having been secured at regular intervals in the meantime, and a negative provocative Wassermann at the termination of the year. While these requirements are not sufficient to prove an absolute cure, they are practicable and should be insisted on in every case.

(2) A negative provocative Wassermann reaction, especially if repeated, indicates that the spirochetes have been destroyed in those parts which can be reached through the circulation of the blood.

(3) The simple complement fixation reaction is invaluable as a control for proper management during treatment. It is of little value in determining a cure.

(4) Nonne's four points of diagnosis afford the only means for justifying the declaration that a cure has been effected. It is not practicable to require this procedure in an examination for life insurance.

(5) An applicant with a history of tertiary syphilis is not insurable under any circumstances.

(6) A practice of directly demonstrating the *Spirochæta pallida* in initial lesions may prove of value to life insurance companies in the future by affording the applicant an opportunity to furnish an authentic statement later on in regard to the nature of some suspicious sore.

(7) It cannot be repeated too often that reports of the different tests are absolutely valueless unless they come from serologists who are known to be competent and reliable. The tests are exceedingly difficult to make and can be carried out only in well equipped laboratories, and a correct interpretation of the results can be expected only from a highly trained and widely experienced operator. A serologist who attends to this work properly will have little time for any other vocation, as the reagents must be freshly prepared and standardized on the day of the test, the whole procedure requiring about five hours.

(8) No statement in regard to the subject of syphilis can be regarded as always true. Further, the companies are not in a position to exact full proof of the eradication of syphilis, and they must, therefore, adopt the additional safeguard of limiting the policies issued to applicants who have had syphilis to forms in which the contract will terminate at about the age of 55, or to policies in which the premiums are rated up. This practice, combined with careful selection, will avert excessive losses when the late and baneful effects of the disease become most destructive to life.

(9) A rigid examination of the cardiovascular and nervous systems must be carried out whenever there is a history of syphilis. This includes the taking of the blood pressure, as lesions of the blood vessels may begin in the secondary stage before the curative agents have arrested progress, or may develop later through the evil influence of nests of spirochetes which remained in spite of treatment.

(10) The lapse of time since the manifestation of syphilis in any form does not diminish its importance. It is quite probable that the excessive losses reported by the companies were due to a considerable extent to less rigid selection on account of the remoteness of the recorded impairment.

(11) A large percentage of relapses occur after incomplete treatment, especially when only one or two injections of salvarsan have been administered. Relapses will occur occasionally even when the course of treatment was vigorous and prolonged. The relapse may not take place until several years after treatment.

(12) No step in the different requirements should be undertaken by a physician as a medical representative of a company. The sample of blood should be collected by the attending physician and sent to a serologist who is known to be unquestionably competent in that line of work. This precaution may avert trouble and lawsuits.

(13) Many applicants will consider the exactions too burdensome or will not be in a position to comply with them, and, consequently, some business will be lost. It may be added in conclusion, however, that the loss of applicants with a syphilitic history will conserve rather than hurt the ultimate interests of the company.

# PRESENT STATUS OF TYPHOID IMMUNIZATION IN THE HOSPITALS AND TRAINING SCHOOLS OF NEW YORK.

By ALFRED MEYER, M.D.,

NEW YORK.

In the spring of 1911, the Medical Board of Mt. Sinai Hospital recommended the introduction into the Training School for Nurses of protective vaccination against typhoid fever. This decision was based largely, though not exclusively, upon the very convincing evidence in its favor which had been presented in this country by Major F. F. Russell of the United States Army. In view, however, of the fact that the method had had but little application outside of the army and only a few training schools for nurses had made limited use of it, it was decided not to make the vaccination obligatory but to call for volunteers.

A committee, consisting of the writer as chairman and Drs. Brill and Mandlebaum, was appointed to start the work. The chairman addressed about seventy-five of the nurses, explaining what had been the experience in the army in regard to the incidence and prevention of the disease, but frankly stating that it was not as yet possible to predict the duration of the protection granted, although the probability was that it would last one year and perhaps two or more.

The number of volunteers at first was small for two reasons: first, because the nurses knew of some violent reactions in others who had previously submitted to the treatment both at Mt. Sinai Hospital and at another institution, although they did not know that these violent reactions were due to excessive dosage; and second, *because they had heard of a nurse's complexion being spoiled.* I have never been able to determine which of these two reasons had the greater influence, but I have my strong suspicions.

Two different vaccines were used for the early volunteers, some receiving that prepared by the army laboratory kindly sent to us by Dr. Russell, and others received that prepared at the Mt. Sinai Hospital laboratory. The method of inoculation followed at the beginning was that advised by Dr. Russell, namely: a total of three injections with ten days' interval, although there were sixteen nurses who had four injections at five days' interval.

Previous to the first injection, a Widal test was made in each case and rectal temperature taken. Nurses with temperature even slightly above normal, were excluded, as were those who were menstruating. The wisdom of the former precaution was shown in the case of one nurse who was *excluded* because of a temperature of only 99.8° when she was to get her first injection. Within a day or two she went to bed with what proved to be typhoid fever, which she was evidently incubating when she volunteered.

Most of the early work, that of 1911 and 1912, was done by Drs. Celler and Fried. That of 1913 by Dr. Brill. The vaccine used in the latter cases was prepared by the New York City Health Department, and the interval between injections changed to seven days with a few exceptions. I have data of 115 nurses showing maximum temperatures after each injection and other clinical notes.

There was no constitutional reaction in 12 (temperature not over 99.4°). There was mild reaction in 74 (temperature not over 100.9°).

There was moderate reaction in 28 (temperature not over 102.9°).

There was severe reaction in 1 (temperature 103°).

Widal tests were made in many cases subsequent to the last injection, mostly ten days later, and I have records of fifty-six nurses with Widal tests of whom forty-eight were positive 1:20 = 85 per cent., and thirty-four were positive 1:50 and over = 34 per cent.

From a study of my temperature charts and Widal reactions, I could not establish a relationship between the severity of a reaction at the time of an inoculation and the subsequent development of the Widal; in fact, repeatedly there were reactions ranging from 101.6° to 102.4° with a negative Widal, and positive Widals with no reaction at all. This is in accordance with a private communication from Major Russell in which he reports a positive Widal 1-40,000 in a soldier who had had no constitutional reaction at all. Repeatedly the Widal was negative after the first injection and became positive after the third.

Out of 115 nurses immunized, only 3 were compelled to go off duty, 2 for one-half day each and 1 for three days. This is a sufficient answer to those trustees of hospitals and schools who fear an interruption of the nursing service from the inoculations. There were local reactions in thirty-five cases—mostly slight, not infrequently after the third injection. There were three cases of urticaria covering the whole body, one after the first injection and one after the third; there were four cases of sore throat, thirteen cases of nausea and occasional vomiting, nine cases of headache and a few cases of diarrhea, but this recital appears more formidable than the facts justify.

I know of but one case of a nurse who developed typhoid fever one year and nine months after inoculation. Through some inadvertence, however, she had received only two in place of the customary three inoculations.* It is problematic whether the third inoculation might not have protected her from the subsequent typhoid; nor can the case be regarded as giving a clue to the duration of immunity when inoculations are properly practised. The case was one of true typhoid as proven by blood culture; the course was a mild one, however.

In December, 1913, I sent a circular of inquiry to the public and private hospitals and training schools of Greater New York asking the following questions: (1) Is typhoid immunization applied among your nurses? (2) house staff? (3) administration staff? (4) If immunization is practised, is it voluntary or compulsory?

I have received replies from forty-seven institutions, which I have tabulated below: In twenty-eight of these institutions, nurses were immunized, the immunization, however, being voluntary in twenty-two and compulsory in only five; compulsory in the sixth institution also only when typhoid patients were being cared for; the interesting point is that inoculations are practised in almost all the larger institutions of the city. In thirty of them the house staffs and in eighteen the administration staffs were immunized, but the immunization was voluntary in all instances.

With such a record from the institutions of the

*On further personal inquiry I learned that the third inoculation was not made because of the violence of the reaction following the first two. This lends additional interest to the case.

TYPHOID IMMUNIZATION IS APPLIED AMONG THE NURSES AND STAFFS OF THESE INSTITUTIONS, AS FOLLOWS:

metropolis it appears to me there ought to be an extensive imitation of our example in hospitals and training schools of other cities, with the hope of hastening the more general introduction of typhoid immunization into civil life.

785 MADISON AVENUE.

**Carcinoma of the Soft Palate.**—W. G. Howarth reports the case of a patient who ten weeks ago noticed a lump at the angle of the jaw, on the left side. It was not painful, but as it increased in size the patient came to the hospital for advice. He had not noticed anything wrong with the mouth or throat. A large mass of glands infiltrating the left sternomastoid was removed. During the last few days considerable discomfort had been experienced on swallowing.—*Proceedings of the Royal Society of Medicine.*

## A CASE OF FACIAL HEMIATROPHY.*

BY M. NEUSTAEDTER, M.D., PH.D.,

NEW YORK.

INSTRUCTOR IN NEUROLOGY, NEW YORK UNIV. AND BELLEVUE HOSPITAL MED. COLLEGE; ATTENDING NEUROLOGIST DIVISION NERVOUS AND MENTAL DISEASES, BELLEVUE HOSPITAL O-P.D.; CHIEF NEUROLOGIST, ST. MARK'S HOSPITAL, O-P.D.

The pathology of the disease is rather meagre but first described by Bergson in 1837 and then by Romberg in 1846 as a clinical entity. It is a rather rare disease and so far there are about 140 cases reported in literature.

The etiological factors so far known are mostly traumata of the face and cranium. Ziegenweidt reports a case after a tooth extraction and Rutten one after removal of adenoids. Often the affection had an infectious disease as a precursor. All observers report that it occurs between the ages of ten and twenty years and rarely after thirty.

The pathology of the disease is rather meagre and most authors consider it as a trophoneurosis beginning in the fifth nerve, in the Gasserian ganglion, while some place the onus upon the sympathetic nervous system. In literature we have so far only seven reports of autopsies. Pissling reports a case in which he found a neoplasm on the convexity of the hemisphere, In Jolly's case there was a multiple sclerosis of the brain. In Von Graff's case of a general paralysis there were found besides the characteristic lesions of Dementia paralytica also a diminution in size of the Trigeminus on the affected side and a gray degeneration of some of the fibers; also a brown discoloration of the pia surrounding the root. Mendel reports the following findings in his case: a considerable thickening of the perineurium of the Trigeminus on the affected side, from which the connective tissue of the endoneurium crossed in considerable number through the nerve bundle. On cross section the nerve fibers appeared normal. In some sections, however, there were evident only few isolated nerve fibers within large areas of connective tissue. The cells of the ganglion were normal but there was evidence of a proliferation of connective tissue. Throughout all the branches of the affected nerve there were evidences of an extensive proliferating interstitial neuritis. Of the soft parts the epidermis was only slightly thinned and in some places the stratum corneum and the rete were affected. The diameter of the cutis between the rete and the outer border of the deeper structures was one-third of that of the unaffected side. The facial muscles showed an atrophy without proliferation of nuclei and also without fatty degeneration. Similar findings are reported by Touche in two cases and in one recently reported by Loebl and Wiesel.

We are, therefore justified, in view of these findings, in assuming that in some cases the facial hemiatrophy is caused by a neuritis of the fifth nerve which affects mainly the descending intracranial roots.

The progress of the disease and its clinical features are so characteristic in my case that I shall discuss these in its description.

O. M., female aet, 41, married. With the exception that her mother died of pulmonary tuberculosis her family history is negative. Personal history: of diseases of childhood she had measles and whooping cough at 3 years of age, from which she recovered without sequelæ. She was a bright pupil in school.

*Presented before the section of Neurology, of the N. Y. Academy of Medicine, Dec. 9, 1913.

At the age of 12 years she received a blow on the forehead with a poker. It rendered her unconscious for a few minutes but, with the exception of a swelling which cleared up in 2 days, she suffered no ill after effects. A few months after this accident the hair near the site of the trauma began to fall out and a bluish streak was formed in the middle of the forehead which is still evident to-day. This forms a line of division between the affected and unaffected side. Five months after the blow active atrophy set in beginning at the line of demarcation on the forehead and extending down over the entire right half of the face simultaneously. There was no noticeable discoloration of the skin of the affected area or any subjective sensory disturbances at that time. This atrophy progressed constantly until the 21st year, when it became stationary. At the age of 16 years the right eye began to be affected growing constantly worse until at 22 she could not discern objects but could distinguish light from darkness. She was operated twice on this eye but without success. At the age of 32 she was seized with an attack of epilepsy of the grand mal type. Since then the attacks came at irregular intervals, once every few months or once a week. The seizures came as a rule at night preceded by a spinal or cephalic aura of short duration—a few seconds. She claims to be able at times to ward off an attack by walking briskly and extending her arms. She has never bitten her tongue but invariably urinates involuntarily during an attack. The convulsions are general; at no time were local convulsions observed. During the last seven months only petit mal attacks would come at the rate of once a month. She is under my treatment for that period of time.

Physical examination; marked hemiatrophy of the entire right side of the face embracing the skin, muscles and bony structures. The temporal muscle seems to be completely gone. The skin is rather thin as compared with the left side of the face and of a yellowish brown hue. The facial muscles and those of mastication are considerably involved and to some extent also the right half of the tongue. The muscle tonus of the affected group is good and its functions are not impaired. The electrical reactions to the faradic and galvanic currents are normal. The bones of the affected side as shown on the *x*-ray plate, are decidedly smaller, the inferior maxilla, the right orbit and the right frontal sinus being nearly half the size of those on the left side, giving the face a peculiar assymmetry. The right eye is considerably sunken in, its cornea is anesthetic. Upper half is clear, the lower one opaque. The opacity occupies the whole of the lower portion of the cornea and ends above in a horizontal edge. Seen with a corneal loop this opacity is superficial, brownish in color with a few white dots

Fig. 1.—Facial hemiatrophy.

and shows vesicles, lime deposits and hyaline degeneration. The iris is adherent to the lens, pupil occluded and lens cataractous. Vision equals to hand movements. She has, an old iridocyclitis. The eyebrow on that side is somewhat sparse. The temperature is on both sides alike and there are no sensory disturbances evident other than pain on deep pressure along the course of the two lower branches of the fifth nerve and in the neighborhood of the upper sympathetic ganglia. The Wassermann reaction of the blood

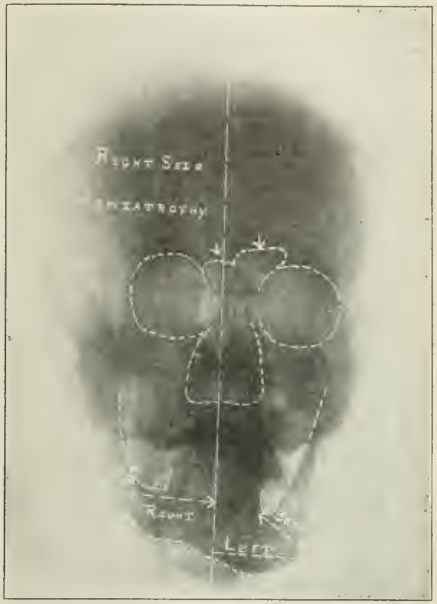

Fig. 2.—Roentgenogram of the case of facial hemiatrophy.

is negative. There is otherwise nothing abnormal about the patient.

The interesting part of the case is that it is extremely rare to have pressure pain along the branches of the fifth, a symptom which is quite marked in this case, and epilepsy as a complication at a rather advanced period of life. One other point of great importance is that the atrophy of the bony structures as hitherto accepted is not borne out by the *x*-ray plate. In bone atrophy we should expect to find a difference in the consistency of the bony structure as compared with the healthy tissue. In this case no such evidence is present. There is absolutely no difference in structure, only the size is one-half. When we remember that the disease started at 12 and as compared with the size of the bones in a normal individual of that age these bones are practically half the size of the adult, it seems reasonable to advance the theory of retardation of growth rather than that of an atrophy.

I am very much indebted to Dr. LeWald for the *x*-ray and to Dr. Jean for his report on the examination of the eye.

1215 Park Avenue.

---

**Industrial Dust and Pneumonoconiosis.**—F. Heim and E. Agasse-Lafont distinguish different varieties of this condition according to the nature of the dust, which may be toxic, infectious, or caustic, or which may be inert, either soft and malleable or hard and resistant. Some cases of penumonoconiosis are chronic, running a slow and prolonged course. This type is caused by inert, hard, and resistant dust. Another type which is known as acute pneumonoconoiosis appears suddenly, running a rapid course. This type is caused by infectious dust containing a pathological agent.—*Archives Generales de Médecine.*

# VISUALIZATION OF THE UPPER INTESTINAL TRACT, BY MEANS OF ROENTGEN RAYS IN CONJUNCTION WITH THE USE OF THE IMPROVED DUODENAL TUBE.*

By I. O. PALEFSKI, M.D.,
NEW YORK.
FROM THE GASTROENTEROLOGICAL SERVICE, MONTEFIORE HOME AND HOSPITAL.

THE duodenal tube, in its short existence, has been accredited with having thrown open new fields in the diagnosis and treatment of some pathological conditions of the duodenum, liver, gall-bladder, and pancreas, and has acquired recognition and place among the many other diagnostic measures in the investigation of lesions of the gastrointestinal tract.

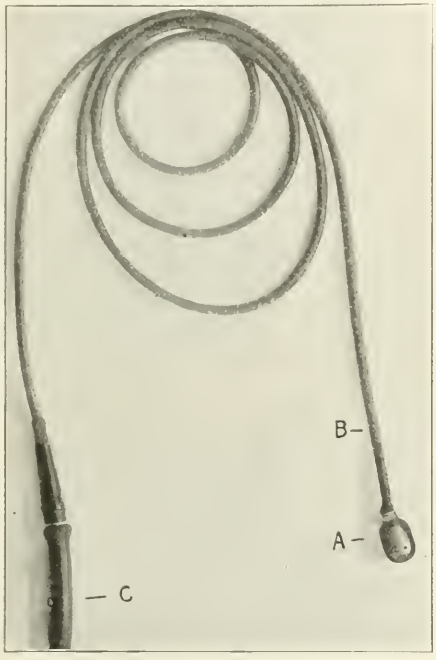

FIG. 1.—The improved duodenal tube.

A number of men in this country and abroad have undertaken a series of investigations by its means and with so many functions already ascribed to it, that if only part of these be found practical, the duodenal tube has already fulfilled its expectations.

The following are some of the conditions in which it is claimed to have a diagnostic or therapeutic value.

*Diagnosis.*—(1) Localization and differential diagnosis of pylorospasm, pyloric stenosis, duodenal obstruction, and duodenitis. (M. Gross.) (2) Diagnosis of duodenal ulcer. (Gross and Skinner.) (3) Removal of a specimen of duodenal contents for bacteriological examination. (Hess.) (4) Removal of a specimen of duodenal contents for the examination of the pancreatic enzymes.

*Read and illustrated with lantern projection slides, before the Section on Medicine, N. Y. Academy, Dec. 16, 1913. An *x*-ray print of only one pathological condition is inserted in this communication, the others being reserved for a future communication.

*Treatment.*—(1) Local treatment of pyloric and duodenal ulcers. (Gross and Einhorn.) (2) Amebic dysentery, with large doses of ipecac through the tube. (Beck.) (3) Transduodenal lavage in the treatment of intestinal fermentation and putrefaction, bronchial asthma, rheumatism, gout, arthritis deformans, constipation (Jutte), and duodenitis. (Gross.) (4) Duodenal alimentation in gastric and duodenal ulcers. (Morgan and Einhorn.) In ptosis and dilatation of the stomach; cirrhosis of the liver. (Einhorn.)

The scope of this paper does not allow me to enter into an analysis of the above claims, further than to state that an experience of over 500 examinations upon 125 patients leads me to regard some of these as mere impossibilities, others as possibilities, and still others as probabilities; yet all of them deserve consideration and thorough investigation. One, however, must regard favorably the following: (*a*) That the duodenal tube furnishes the best means of procedure in ascertaining the functional activity of the pancreas by examining a fresh specimen of duodenal contents for pancreatic enzymes. (*b*) Duodenal alimentation in gastric and pyloric ulcers and vomiting due to gastric and pyloric lesions (*c*) Local treatment of duodenal ulcers, duodenitis, and catarrhal jaundice, the method of which is yet to be perfected. (*d*) Suction of the common bile duct in the impairment of the flow of bile when such is not due to obstruction by gallstones. (*e*) Intestinal therapeutics, the nature and method of which is yet to be established.

In this communication I desire to submit for consideration the subject of visualization of the duodenum and commencing jejunum by means of Roentgen rays in the conjunction of the use of the improved duodenal tube in the diagnosis of atypical chronic or obscure lesions, situated in this part of the alimentary canal, when their presence is suspected or cannot be detected by the well-established methods. It must be remembered that *x*-ray investigations of the upper intestinal tract, for diagnostic purposes, are not always satisfactory, owing to the fact that this part of the intestinal canal is insufficiently filled with the impervious substance, at any given time, to show its course, shape, and size upon an *x*-ray plate. Hence the fluoroscope enabling the direct examination, but also not quite satisfactory, is resorted to by the investigator. About a year and a half ago it occurred to Dr. Wachsmann, Medical Director of the Montefiore Home, and myself, that the course of the duodenum and the commencing jejunum may be made visible by filling the duodenal tube with a suspension of bismuth following the aspiration of a specimen of duodenal contents, the duodenal tube being in duodenum or jejunum. Since then every duodenal case that came under observation at the Montefiore Home was thus examined with the result that in a number of cases this procedure not only aided in the deliberation of some diagnosis, but in some instances it proved to be the only means with which we learned of the correct condition, later verified in all operative cases but two.

In direct bearing upon this subject I desire to emphasize the following:

1. Correct duodenal instruments and speedy intubation. No one will ever advance in this skillful and tedious work until he learns of the difficulties encountered during a duodenal examination, and no duodenal instrument will fully meet its task

unless its construction be based in a view of overcoming these difficulties. It is in this respect where the original duodenal tube has failed and its shortcomings are fulfilled by the modified duodenal tube and gastroduodenal tube, both of which I described

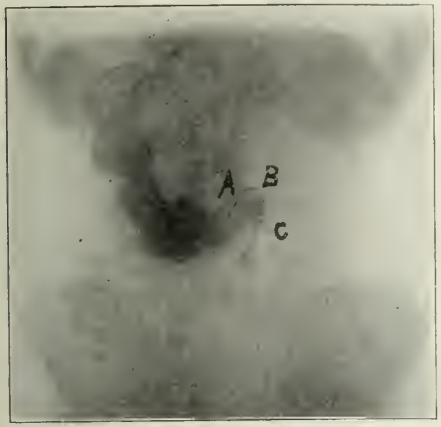

Fig. 2.—The duodenal-tube at the Ampulla of Vater. A, First portion of duodenum; B, curve formed by the junction of first and second portions of the duodenum: C, second portion of duodenum; the stomach filled with bismuth shows deformity in the larger curvature; duodenum unaffected.

in the *New York Medical Journal*, October 18, 1913 —an outcome of a previous experience of a few hundred duodenal examinations. (Fig. 1.)

2. Evidence showing the duodenal tube to be in the duodenum. Before taking an *x*-ray exposure of the duodenum and jejunum, the operator must ascertain that the duodenal tube be *in situ*. The "retraction sign" and "sense of resistance," so much emphasized by others, are of little value, inasmuch as the same will be experienced when the ball of the duodenal tube is in the grasp of the pylorus and the tube itself is coiled up in the stomach. I am, therefore, employing the following three methods: (*a*) Aspiration of a specimen of clear, neutral, and bile-colored duodenal contents following a previously aspirated specimen of colorless hydrochloric-acid contents, is positive evidence that the duodenal tube is in the duodenum, as a specimen of regurgitated duodenal contents, is almost always turbid and usually acid in reaction, free hydrochloric acid being present. (*b*) Upon inflating with a bulb attached to the outer end of the duodenal tube, if the latter is still in the stomach, the epigastrium will become distended and tympanitic and the patient will experience discomfort followed by immediate belching. On the other hand, if the tube is in the third portion of the duodenum or beyond this point the lower abdominal quadrants will become distended and tympanitic; the epigastrium will become depressed, and the patient will neither belch nor experience any discomfort whatsoever. (*c*) Auscultatory inflation. Auscultation while inflating will elicit sounds characteristic to each of the viscus. If the tube is still in the stomach, on auscultation over the epigastrium the sounds will be of a loud, gurgling quality as: gr-r-r-r. If the tube is in the duodenum, on the other hand, the sounds will possess a distant hissing quality as: ss-ss-ss, more distinct on auscultation over the left hypochondrium.

3. Duodenal-tube obstruction. By this term I mean to include conditions in which the improved duodenal tube meets with apparent hindrances during its transversing the duodenum and which may or may not be accompanied by gastric stasis or obstruction. The normal duodenum is horseshoe shaped with its convexity toward the extreme right. The duodenal tube will reach the Ampulla of Vater within a period of one or two hours, as evidenced by the aspiration of clear, neutral, bile-colored duodenal contents, provided the normal curve of the duodenum be intact. In some conditions, however, as in adhesions involving the first and second portion of the duodenum, the curve of the latter becomes distorted and angulated (Fig. 5) and the ball of the

Figs. 3 and 4.—The duodenal tube outlining the course of the normal duodenum and the commencing jejunum; D, larger curvature of the stomach; E, course of jejunum; F, umbilicus; G, duodenal tube along lesser curvature.

duodenal tube thus will be caught and lodged in some of these angles or pockets for many hours, during which time the tube will aspirate mixed gastroduodenal contents of a greenish, turbid acid liquid, simulating the yolk of an egg. In some of

these conditions, on fluoroscopic examination, six hours after a bismuth test meal, the stomach will be found completely empty, showing that while the obstruction is not complete enough to delay the passage of the semi-liquid acid chyme, it is, however, sufficient to delay the passage of the solid ball of the duodenal tube. In such conditions, hence, it is highly desirable to learn of the course and shape of the duodenum and jejunum, which can be accomplished as follows:

*Procedure.*—The introduction of the improved duodenal tube and the aspiration of duodenal contents are accomplished in the manner as outlined in the article above mentioned. On aspiration of clear, neutral, bile-colored duodenal contents, usually occurring within two hours, the operator then fills and distends the duodenal tube with a suspension of bismuth made as follows: Thoroughly stir up with a glass rod, for a few minutes, about a half ounce of bismuth subnitrate into 3 ounces of

Fig. 5.—Duodenal tube outlining the course of the duodenum and commencing jejunum in a case of perforated duodenal ulcer; A and C meeting at an angle; B, which is drawn up to the fundus of the gall-bladder. The jejunum, E, is adherent behind the posterior surface of the stomach as far as D; F, duodenal tube along lesser curvature while in the stomach; G, umbilicus.

milk to a fine suspension. Strain the latter through a funnel and absorbent cotton to exclude coarse and undissolved particles of bismuth. Then fill a 15 c.c. glass syringe, terminating into a point, with the strained suspension and inject the latter into the duodenal tube until a resistance is felt, usually after the injection of about 10 c.c. The distal end of the tube, then, is clamped to prevent the escape of the bismuth. The patient now drinks about a glass of milk containing an ounce of suspended bismuth by mouth. This is necessary in order to differentiate the stomach from the duodenum. The exposure is then made with the abdomen in apposition with the film side of the *x*-ray plate, in a standing posture whenever possible. The duodenal tube then is removed and cleansed.

*Interpretation of Figures.*—A considerable number of *x*-ray plates of the duodenum with the duodenal tube *in situ*, distended with a suspension of bismuth, have established the fact that in Fig. 2 the duodenal tube outlines the normal course of the duodenum. A and C representing the first and second portion respectively. The smooth curve, B, formed by the junction of the first and section portions of the duodenum, is especially to be noted. When this be intact the improved duodenal tube will reach A within a period of 1 hour and, on aspiration, watery, colorless or slightly greenish, neutral or faintly acid contents will be obtained. It reaches B, or the Ampulla of Vater, within a period of 1½ to 2 hours, as evidenced by the aspiration of golden greenish, clear, neutral, bile-colored contents. (Fig. 2.)

*Figs. 3 and 4.*—Here the duodenal tube outlines the normal course of the duodenum as well as that of the commencing jejunum. The relationship between the latter and the larger curvature of the stomach, particularly, is to be noted, namely, that the one is seen below and along the other. (D and E, Figs. 3 and 4.)

*Fig. 5.*—The duodenal tube outlines the course of the duodenum and the commencing jejunum in a case of a perforated duodenal ulcer with adhesions between the duodenum and the fundus of the gall-bladder and between the jejunum and the posterior surface of the stomach. The curve formed by the junction of the first and second portions of the duodenum, seen in Figs. 2, 3 and 4 is represented by the sharp angle, C. The commencing jejunum is not seen running below the larger curvature but, as found at operation, is hidden high and behind the posterior surface of the stomach coming into view at D. In this case the duodenal tube has reached the Ampulla of Vater not before 16 hours, during which time it aspirated gastroduodenal contents, turbid, acid reaction, containing occult blood. I term this delayed passage "Duodenal-tube obstruction," in view of the fact that the *x*-ray examination 6 hours after a bismuth diet revealed no gastric stasis or obstruction, the stomach having been found normal in its shape and size.

Perhaps the history of this case, briefly told, will emphasize the importance of this method of examination.

H. C., at the age of 16, was admitted into a hospital complaining of epigastric pain and abdominal cramps, starting about one-half hour after meals, at intervals of three to four months, each attack lasting about ten days. After four weeks' stay in the hospital he was discharged improved, with the diagnosis of hyperchlorhydria. He was re-admitted one week later with the same complaint when left herniotomy was performed, in the belief, that the left inguinal hernia, then present, might be responsible for the symptoms. A few months later he was admitted into another hospital, where *x*-ray examinations of the gastrointestinal tract and of the left kidney were made and proved to be negative. The patient was then discharged with the advice "to better look for some job." The idea that this might be a case of "Hospitalitis" apparently occurred to the physician in charge, owing to the fact that the patient was a mere boy without parents, penniless and faced a rather trying start. The patient then entered a third, and, later on, a fourth, hospital but without improvement until he, finally, came to the Montefiore Home with a diagnosis of "morphine fiend." The patient was then examined by Dr. Harlow Brooks, who thought of the possibility of a duodenal ulcer which probably escaped recognition by the ordinary methods of examination. I then examined the patient by the method described above and the true condition made itself apparent, namely: distortion of the course of the duodenum and the commencing jejunum by adhesions probably resulting from an old perforated ulcer. Exploratory laparotomy was then performed by Dr. Charles Goodman which revealed a scar of the size of a dime, situated in the second portion of the duodenum and adhesions between the latter and the

fundus of the gall-bladder and between the jejunum and the posterior surface of the stomach (Fig. 5). Gastroenterostomy was performed, followed by an uneventful recovery and, at present, nine months hence, the patient is enjoying good health.

At the Montefiore Home we met with a number of other patients in whom the true condition could not definitely be made out until examined by the above method. The nature of the cases and findings will be reported elsewhere in due time. Considering the short existence of the duodenal tube, its accomplishments and possibilities, it seems as if we are now entering upon an era of great expectations in gastroenterology.*

In conclusion, I desire to express my thanks of appreciation to Dr. S. Wachsmann, Medical Director of the Montefiore Home, whose cooperation has enabled me to carry on my researches in gastroenterology.

Gun Hill Road and Jerome Avenue.

## ON THE ISO-SERUM TREATMENT OF THE INCOERCIBLE VOMITING OF PREGNANCY.

By CECIL KENT AUSTIN, M.D.,
PARIS, FRANCE.

Among the manifold pathological conditions in which a pregnant woman is liable to find herself, there is none that seems so positively lamentable as that known as incoercible vomiting. Others may be more serious *quoad vitam*—placenta prævia, or eclampsia; but neither of these gives the impression of being such a *senseless* performance as incoercible vomiting. A young woman marries, in splendid spirits, health, and physical state, begins to vomit in three or four weeks, and, at the end of ten or twelve, finds herself reduced to an absolute wreck, her life in danger, and obliged to undergo artificial abortion! The picture she then presents is simply pitiable; all the contours of her figure are gone, such patients sometimes decreasing as much as one-third in weight, falling off at the rate of a pound a day; her skin is sallow, dry, and powdery; she may either have profuse ptyalism, or dry lips and parched mouth; she vomits, even at the thought of food, fifty or sixty times a day perhaps, two liters of gastric fluid; there is constant headache, rapid breathing, a quick pulse of low tension, and deranged mentality, and the urine may be reduced to two or three hundred gram. All of this calamitous state has descended on a young and perfectly healthy woman in the accomplishment of the normal and primordial function of her sex, the perpetuation of the species!

I made use of the term "senseless" in the preceding paragraph, in referring to this condition. What I meant to imply was this: One of the cardinal preoccupations of Nature has been to insure that by no possibility the continuation of any species shall be endangered. It is for this purpose that the sex instinct is the dominant feature in life, the pivot about which the entire universe revolves. This care on the part of nature is likewise demonstrated by the wild lavishness with which the reproducing sex is provided with the raw material, if I may so express myself:—witness the roe of one cod, or the 'keys" on one ashtree. The anatomist Sappey, once endeavored to calculate, with the help of the microscope, the number of ova in a woman's ovaries, and reached the remarkable total of 700,000, of which not more than a couple of dozen could ever fulfil the purpose for which they were destined.

*"Purse Stringing of the Small Intestines," etc., *New York Medical Journal*, April 18, 1914.

This being the one aspect of the question—the provision of seed in an almost inconceivable superabundance—it seems so inexplicable that, on the other hand, nature should have surrounded the bearing of children with such a phalanx of drawbacks, inconveniences, disabilities, disorders of function, ailments, and illnesses, that if women were not the remarkable creatures they are, they would never go through a second pregnancy after the experience of a first. There is nothing more striking in nature than this attitude of women toward child bearing, though in saying this I do not lay claim to any originality, the fact having already occurred to the Apostle John nearly two thousand years ago! For instance, I once had a patient who began her first pregnancy with four months of continuous and serious vomiting, and closed it with eclampsia, in which both she and the infant might perfectly well have succumbed; yet it was not a week before she was referring to what she intended to do the next time she became *enceinte!* Where is the man who could be found to act in a similar manner? In this respect, at any rate, women have something in their composition that is totally lacking in their male biological complement.

If this is the case with the bearing of children, what can we say about actual parturition, about the proposition that is then before the woman—to drive a well-developed fetus of 8 pounds, more or less, through a series of four tight rings, hard and soft, without damage to herself or it, mechanical disproportion being possible at any one of them, as regards size or position. In all situations in life there is no poorer policy than to leave no margin for the unexpected; but the childbirth apparatus is one that only works well when everything is *just right*—and how often is that the case? The perils at this stage are infinite, and here again nature appears to have taken back with one hand all the bounty so freely bestowed with the other—700,000 ova—and yet such a multitude of pitfalls laid for the one or two dozen that may possibly serve their purpose. The whole process seems strangely inconsequential. The truth is, and there is no reason for hiding it, that from the woman's standpoint procreation is not a very brilliant affair from start to finish, and that if they were not made of pretty good stuff they would never put up with it.

The frequency of vomiting among primiparæ is very great, and the condition has also this curious peculiarity that it occurs almost exclusively among primiparæ. This point naturally attracted attention from all time, and the theories advanced to account for it have been legion, which, in accordance with the well-known law, indicates that none of them have been of very much value. One of the latest in the field, however, one that is extremely seductive in that it has led to a form of treatment in thorough concordance with the reigning medical doctrines of today, is that championed in France by Fieux, professor of obstetrics at the Faculty of Bordeaux, though it really originated in Germany. This theory is that during the stage in which the chorial villosities flourish, and up to the time when they all disappear except the portion that has given rise to the placenta, the syncitial cells that cover these villosities secrete a species of poison which, when taken up in the maternal circulation, intoxicates the mother and produces the early vomiting of pregnancy. The presence of this toxin determines an antibody-reaction, and on the more or less prompt and effective response on the part of the mother's organ-

ism depends the degree of vomiting; if early and vigorous the patient only experiences a little squeamishness that soon passes off; but if tardy or lacking the serious forms of vomiting occur. According to this theory, also, the relative absence of vomiting in later pregnancies is due to immunity acquired through the elaboration of these antibodies.

The idea that forms the basis for this theory—that the fetus is a species of dangerous parasite, noxious to its mother and against which she is forced to defend herself by the same sort of biological reaction as she would bring to bear against the invasion of some bacterial foe—is unquestionably one that profoundly shocks all one's sense of reason. But in medicine there is little room for sentiment, and we have to be guided by facts alone, and the curious sanction of Fieux' theory are the results that have been obtained from the recent iso-sero-therapy of serious vomiting movement, which has also been extended to the other autotoxic accidents of pregnancy. The authors of this treatment said to themselves: "If we go on the assumption that the various forms of the autointoxication of pregnancy are due to deficiency in the patient's blood of certain substances which in normal cases are present in suitable amounts, would it be feasible to make good this deficiency by injections of serum taken from a normal pregnancy at a corresponding stage of development? And it cannot be gainsaid that the results obtained by putting this idea into practice have been most striking. The cases so far reported have, it is true, not been very numerous; the method is still in its infancy, having first been used only in 1910; and there are unquestionable drawbacks to the idea—it may not always be found easy to procure a donor, or to be positive as to the innocuity of a donor's serum. But still, enough material is now available to supply a general view of the question, at any rate as a preliminary to a more extensive study of the subject, and for this reason the following summary is given of the cases so far reported. In view of the defective organization of the faculty library here this list cannot claim to be complete. Still, it is believed that no very important papers up to the summer of 1913 have escaped notice.

I.—Mayer and Linser (Tübingen), *Münch. med. Woch.*, 1910, December 27.—Herpes gestationis. Vesicles and bullæ, serous or purulent; fever, prostration and albumin. Fifty per cent of these cases prove fatal. Woman six months pregnant, very pronounced case. Injection of 10 c.c. of serum from a healthy but non-pregnant woman produced no change. Three days later, 10 c.c. were given intravenously, from a normal eight-months pregnancy, and again three days later 20 c.c. from another healthy pregnant woman. The temperature began to fall immediately after the first injection from a pregnant woman, and became normal the day after the last injection. The dermatitis dried up and disappeared, and in a few days the patient left the hospital. Five weeks afterwards, recurrence; patient came back to hospital; 20 c.c. intravenous, with same favorable result.

II.—Freund (Berlin), *Med. Klinik*, 1911, March 5.—1. Incoercible vomiting, icterus, album. psychosis, prurigo gestationis. 5-para in her third month. On January 14, 24 c.c. intravenous, serum from a 1-para in her second month. Manifest improvement on the third day. January 21, worse again. Another injection of 25 c.c. from a 2-para in her ninth month. All symptoms disappeared.

2. Three serious cases of eclampsia, all recovered; but they were bled as well. One of them was an extremely grave case.

III.—Rübsamen (Bern)., *Zentralblatt für Gynäk.*, 1911, May 27. Bad general condition, slight icterus, gall-bladder and right renal region sensitive, albumin in urine, pruriginous erythema of right forearm, T. 39°, p. 130, 5-para, 6-7 months pregnant. 15 c.c. intravenous, serum from a 1-para in her ninth month; injection well-supported, but urticaria for several days. Result of treatment negative, so far as could be seen, condition even grew worse; but finally, normal confinement and woman recovered.

IV.—Le Lorier (Paris), Acad. de Méd., July 25, 1911. Incoercible vomiting. Woman at two and a half months, lost 23 kilos in two months, one-third of her weight, pulse constantly over 100, could retain nothing, solid or liquid. Injection of 12 c.c. and, two days later, of 15 c.c. of serum taken from a woman who had had several children and who was now near term. The result was extremely satisfactory and rapid, vomiting decreased very quickly, and in six days the pulse had fallen below 100 and the weight increased 500 grams.

V.—Mayer (Tübingen), *Centralbl. f. Gyn.*, 1911, Sept. 16.

1. Acroparesthesia, tingling and insensibility of finger ends, which were slighly swollen. 1-para near term. Two days after an injection of 10 c.c. from a normal, pregnant woman the trouble had entirely disappeared.

2. Herpes gestationis in a 6-para. Condition grew worse after parturition. Intra-musc. injection of 20 c.c. of serum from a normal pregnancy. Improvement appeared at once. 36 hours later, second injection of 35 c.c. followed by complete recovery.

3. Eclampsia, 2-para, 16 attacks, coma. 20 c.c. intravenous, serum from a normal pregnancy; slight improvement, but attacks recommenced in a few hours. Again 20 c.c. intravenous. Coma disappeared and patient urinated. Again 20 c.c. and all trouble ceased and confinement was normal.

VI.—Freund (Berlin), *Deutsch. med Woch.*, 1911, Dec. 28.—Pruriginous polymorphous erythema in a 1-para at eight months. Did not disappear after delivery. Tried to replace human by horse serum; 25 c.c. intravenous, fresh horse serum. Marked reaction, headache, and fever; but the eruption diminished rapidly and disappeared at the end of two days.

VII.—Fieux and Dantin (Bordeaux), Soc. d'Obst. et de Gyn. de Paris, 1912, Jan. 8.—Incoercible vomiting at 2½ months; very serious condition. Two injections of serum from a normal pregnancy of about 2-3 months, were followed by rapid recovery.

VIII.—Fieux and Dantin (Bordeaux), Soc. d'Obst. et de Gyn. de Paris, 1912, April.—Incoercible vomiting. This patient had incoercible vomiting at her first pregnancy, which ended in miscarriage. Her second pregnancy was normal. In this, her third, there was serious vomiting. One injection of human, non-pregnant serum did nothing, save to lower the pulse a little; but it soon went up again to 104-12. A second, from a normal pregnancy of about 3 months, was followed by depression, and the pulse went below 100 again; 24 hours after the injection the vomiting decreased, to stop altogether in a week. Even after four days the patient was already back on a normal diet.

IX.—Veiel (Darmstadt), *Münch. med. Woch*, 1912, Aug. 27.—Herpes gestationis. In the sixth month of her second pregnancy this patient had pruriginous erythema, followed by a bullous eruption. This was cured by ordinary means in seven weeks. The next three pregnancies were normal. At this, her sixth, toward the end, very pruriginous bullous eruption, without alb. 10 c.c. hypod., serum from a normal pregnancy in its 9th month. Next day, slight improvement; but two days later, bad as ever. Six days after the first injection, 20 c.c. from the same donor. On the following day, patient's condition quite transformed, prurit. had ceased, no new bullæ, and temperature normal. Improvement was maintained, and delivery was normal. Three days later, fresh eruption; but farther injections were deemed unnecessary.

X.—Fieux (Bordeaux), *Ann. de Gyn. et d'Obst.*, 1912, p. 718.

1.—At her first pregnancy this woman had such serious vomiting that abortion had to be performed at three and a half months. At this, her second, vomiting almost as bad. Toward the end of the sixth week, 20 c.c. horse serum; this reduced the vomiting somewhat, but intolerance remained the same, the pulse rose to 100, and urine decreased. 4 days after the first injection, 15 c.c. hypod., serum from a normal, 3-mos. pregnancy. 36 hours later, sudden improvement; vomiting ceased, urine increased, food was retained, and patient gradually returned to a normal state.

2. At her first pregnancy, such serious vomiting that artificial miscarriage was induced at the end of the third month. Her second pregnancy showed vomiting

from the very start, and it went steadily from bad to worse. Towards the end of the second month, 20 c.c. horse serum hypod.; some improvement, but patient's condition very grave, pulse filiform, 104-110. 48 hours later, 15 c.c. horse serum. Next day, sudden and astonishing improvement; vom. soon came to an end, and the pregnancy gradually became a normal one.

XI.—At the XVth session of the Soc. d'Obstétrique de France, held in Paris, October 10-12, 1912, Oui (Lille) reported a case. Very serious vomiting; patient lost five kilos in one month, pulse 140; and other treatments had failed. On Sept. 28, 10 c.c. of the serum of a normal, two-months pregnancy were injected, with success. The patient then had some gastric upset, and vomiting began again; so on Oct. 2, 10 c.c. of a normal, three months pregnancy were injected, again with success. This case, however, is not completely demonstrative, since on Oct. 22, the woman expulsed a dead fetus.

(This case was also reported in the *Bull. Soc. d'Obst. et de Gyn.*, 1913, March, p. 192).

XII.—At the same XVth session, Le Lorier (Paris), reported three more cases of the vomiting of pregnancy treated by this method. The first ended in total failure, and artificial abortion had to be resorted to, to save the patient. The second was a complete success. In the third the vomiting ceased; but it was found that the fetus had succumbed.

XIII.—Freund (Berlin) has recently published an article on the serotherapy of the Dermatoses and vomiting of Pregnancy, and of Eclampsia, in the *Zeitschrift für Gebürtshülfe und Gynäkologie*, Bd. LXXIV, 1913; but I have not yet been able to lay my hands on this periodical.

XIV.—A. Franz (Gratz) *Z-bl. für Gyn.*, Vol. XXXVI, p. 913-916.—In order to turn the difficulty of obtaining the serum of normal pregnancies for use in cases of parturient autointoxication, Franz collected aseptically the blood from the umbilical cord in a number of deliveries, centrifuged it, filtered it through porcelain, and stored it with chloroform in small bottles in the dark. This serum he used with striking success in a case of exudative polymorphous erythema in a woman very near term.

XV.—F. Woly (Gelsenkirchen), *Berl kl. Woch.*, 8 Sept., 1913, p. 1661-2. The author describes still another case of pruriginous dermatosis at eight months rapidly cured by the serum method. But the peculiarity of this instance was that the serum was taken from a woman who had been delivered two weeks previously. The antitoxic substances are therefore still present in the blood at that late stage.

XVI.—Finally, Dantin (Bordeaux) has resumed the question in his thesis (1913): "La sérothérapie dans les vomissements graves de la grossesse et dans les dermatoses gravido-toxiques."

From these reports it will be seen—if we set aside the two cases in which horse serum was used, and Freund's last paper, of which the details are lacking—that the iso-serum treatment of the autointoxication of pregnancy has been applied in twenty instances, as follows: Vomiting, 9 (one failure); eclampsia, 4; herpes gestationis, 5; less well-defined conditions, 2 (one failure); and that with eighteen patients it succeeded, sometimes quite dramatically, while with only two did it result in failure.

The marked success of these injections in the serious vomiting of pregnancy (eight out of nine), when taken together with the generally grave character of this disorder and our almost total lack of any other efficient means of combating it, appears to indicate that in this new method we have acquired a therapeutic agent that may prove of great service. The treatment has in reality only one drawback, the difficulty of being *certain* of the innocuousness of the donor's serum; for as to the possibility of not being able to find a donor for a given case, which has been advanced, this will never prove a serious obstacle. The touching solidarity between women in all matters of child bearing is so infinite that there is no very great danger of any one of them allowing it to be said of her that for lack of a few grams of blood from her arm she had jeopordized the existence of another woman or of that woman's offspring.

20 Rue Chalgrin.

## CANCER STATISTICS.

By A. L. BENEDICT, M.D.,

BUFFALO, N. Y.

So much depends upon statistical evidence in judging of the nature, prevalence, and etiology of an imperfectly understood disease that the following compilation from the recently published Mortality Report of the United States Census for 1911 may be of interest. The statistics are based on the registration area, and their accuracy, in some respects, may be judged from the fact that, of the total of 839,284 deaths, only 1,296 were unknown as to age, while of the cancer deaths the ages were unknown in only 41 cases. The total deaths from cancer and other malignant tumors numbered almost exactly 44,000, about 5 per cent. of deaths from all causes.

A very important item in drawing conclusions as to the essential incidence of a disease like cancer, its relative frequency, mortality, etc., is the distribution of population by age and the conflicting influence of other diseases. In this study we shall compare merely the deaths from cancer (in the necessarily inclusive sense of the census reports) with the total deaths at any given age. This is not an absolutely correct criterion. A person may have cancer and yet die of a different condition, quite accidental or incidental. In the broader sense, especially if we regard cancer either as an infection, to the successful implantation of which certain individual conditions must be fulfilled, or as a constitutional disease in the more exact sense, a person not yet cancerous in the clinical sense, may have the inherent conditions necessary for its development and may be prevented from having cancer, by death due to some other condition. These qualifica-

tions, undoubtedly correct in theory, are not, however susceptible of quantitative analysis.

The proportion of deaths from cancer, with reference to the total deaths at any given age, are (by five-year periods) as follows:

Some general comments may be in order. There is a considerable excess of male deaths, 457,308 for the registration area, as against 381,976 females. This is partly accounted for by the slightly higher male death rate, 14.7, as against 13 per 1,000 population of all ages, but to a much greater degree by the general preponderance of males, due, probably, mainly to the disturbing factor of immigration. There is a general impression that, having passed the vicissitudes of sexual life women enjoy a greater longevity than men, probably on account of their more quiet and sheltered life, and this impression is shown to be correct, but at a higher age than is commonly supposed, namely, after 80. The greater number of deaths of males than of females for the first fourteen years of life can scarcely be attributed to excess immigration of males, nor to any essential sexual difference, nor, before the fifth year, to any difference of habit of life. It must indicate a relative excess of male births, as is corroborated by statistics which, however, are not regarded by the census bureau as very exact. The enormous mortality of young children, the risk of death up to the age of five being approximately equal to the risk for the next 35 years put together, is to be regretted, and is being considered to a large degree by the medical profession and sociologists.

In examining the mortality statistics with special reference to cancer, it may be pointed out that the figures for early childhood show no characteristic sexual difference, and a very small incidence in spite of the fact that sarcoma, Hodgkin's disease, and some other conditions are undoubtedly included. If the hypothesis that carcinoma and sarcoma—or other lymphatic tumors, and possibly some forms of leucocythemia—are essentially the same disease (usually by this hypothesis held to be an infection) occurring in different structures, this inclusion is strictly justified. For later years the disturbing element of inclusion of sarcoma, etc., is insignificant, not, indeed, as great as the undetermined factor of error of diagnosis for which no basis of correction is available except by recourse to statistics on such a small scale as probably to introduce a still greater error. It may be pointed out in this connection that the census statistics based on the registration area are probably quite reliable, at least allowing for the neutralization of opposite errors in diagnosis, and that they are of sufficient magnitude to warrant very accurate general conclusions so far as the law of chance is concerned, up to the extreme limit of human life, the minimum series being 133 male deaths at the age of 100 and upward. In this series, only two deaths occurred from cancer, and it is obvious that fractions of a per cent. cannot be considered significant here, although the general conclusion is both concordant with the other statistics in the series and sufficiently exact for practical purposes.

Inspection of the various series of total male and female death rates of cancer (which, it should be noted, are with reference to the deaths from all causes of the respective age groups as 100 per cent., not with reference to population), shows an incidence of cancer of less than 1 per cent. below the age of 25, this incidence being not reliably shown from census statistics for reasons already given. Beyond this age we note a very regular increase in cancer mortality up to maxima differing by ten years between the sexes, and on account of averaging these two elements, differing by five years if the aggregate of both sexes is contrasted with either sex. Following this, we find an almost equally regular downward progression. This phenomenon is, generally speaking, corroborative of the commonly held opinion, but it should be emphasized that the diminishing tendency to cancer after the climacteric is much more gradual and regular than many, including the writer, have supposed. Undoubtedly, many have failed to realize that the maximum incidence of cancer death occurs at least five years after the average time of the menopause, and five years later still, in men; this statement being true with some possible minor qualification, whether we refer to the proportionate or to the actual cancer mortality. It has been said, epigrammatically, that cancer—and some other diseases, as myxedema, diabetes, etc.—tend to occur in the youth of senility, the same idea being expressed more technically in the explanation that at the beginning of senile changes there is a state of excessive irritability of epithelium, which predisposes to cancer. The statistic evidence detracts considerably from the validity of this explanation, or else cancer has a longer latent stage than is often supposed.

The very gradual and steady decline of cancer mortality as age advances may be explained as due to the constantly increasing removal of susceptible individuals, either by cancer itself or by some other, accidental or incidental, condition. It is obvious that all who have been killed by any form of violence, at any age, would, if they had survived, have shown a general average incidence of cancer identical with that actually observed. It is only less obvious that all who have died of any other condition, infectious or otherwise, would, if they had lived, have shown precisely the same cancer incidence, unless something inherent to the disease of which they died, or something inherent in themselves which predisposed to that disease, would have modified their susceptibility to cancer. The only way in which this point can be determined is by carefully noting the susceptibility to cancer in others who have survived similar diseases, and there are no statistics available to determine the actual facts. Barring such determinations it is obvious that the predisposition to cancer must be gauged by its incidence proportionate to comparable age and sex groups.

Analogously, the question as to whether cancer is genuinely on the increase or not, can be accurately determined only by comparison at intervals of years of deaths from this disease, with the totals for respective age and sex groups, and it is even desirable that other details, particularly fecundity, implied to some degree by the social state of women, race, etc., should be separately considered. Here, again, statistics are lacking. The report on Mortality Statistics for 1911 (page 33) gives some interesting data with regard to increase of cancer, with reference to total population. On the average, this increase is 25 per cent. for all ages over 25 (at death, the population being of mixed ages). On inspecting the table of cancer mortality given in this article, it will be noted that the prolongation of life by five years would account for much more than this increase of cancer, up to the age of 50, for the aggregate of both sexes. The average duration of life

has been very materially increased in the last generation, but how much this increase depends on diminution of mortality in infancy and early childhood, and how much in adult life, is not so easily determined, and in the absence of definite evidence on this point, no further conclusion can be drawn than that a very moderate extension of life would account for a very large increase in cancer. However, we can scarcely compare the present with earlier statistics on a large scale and say whether or not the present cancer mortality is what may be termed normal or not.

These statistics point to a method for settling the question of heredity in cancer. It is obvious that, on the average, any family can be judged as to hereditary tendency to cancer only after an age is reached at which cancer occurs with sufficient frequency to reduce the element of chance to a minimum. Approximately, one in ten of all persons, of both sexes, between the ages of 45 and 69, dies of cancer, if at all in this period. This statement may be modified by reference to the table according to sex and other age groups. For example, if one could collect statistics of grandmother and numerous sisters, mother and numerous sisters, and one's own sisters dying between the ages of 40 and 69, one-sixth would normally die of cancer. To be of any value, such statistics would have to include a large number of separate families showing on the one hand more than one cancer death, and on the other hand none at all. It is obvious that a long-lived family would normally show much more cancer than a short-lived one. The late development of cancer is also an objection to the theory of heredity, though not a positive one, since we have little knowledge of the actual duration of cancer in the body. It should also be understood that if one includes in the term family more than two or three generations it is so intricately connected with other families that conclusions are scarcely justified, unless, indeed—what is extremely improbable—the genealogic implication that a family depends upon heredity from a male, is scientifically correct. To emphasize this point it is only necessary to call attention to the fact that any one's ancestors progressively double in going back from one generation to the next and reach beyond a thousand ancestors in the tenth generation, not to mention intermediate generations and collaterals.

During active sexual life and the climactertc, including the period up to the complete cessation of functional activity and of its after effects, it is well known that cencer of the female genitals and the breasts is especially frequent, amounting to over 50 per cent. of all cancers in women, in the decade 40-49. Subtracting these cancers, the mortality rates for the two sexes for respective ages differ much less and, indeed, are slightly less for females in the period 25-29 and after 80. The cancer mortality for females corresponds fairly well to that of males, if we compare between the ages of 35 and 75, the male mortality of the next higher age group. This fact may be interpreted to substantiate the popular notion that women age more rapidly than men during this period. The higher mortality for females, even after excluding the essentially sexual glands and epithelial tissues may be construed as (1) a special sexual predisposition; (2) as indicating false diagnosis in ascribing tumors originating in the parts to adjacent parts; (3) as indicating some influence on the part of these organs, either as receptive of infection or of the nature of a hormonic action, which determines cancer elsewhere. As cancer of the male breast is not unknown and as vestigial female parts and analogues to male vestiges in the female exist in the male, it is not entirely fair to subtract cancer of the breast and genital organs in estimating the true, residual female tendency to cancer but the error is slight.

On the other hand, it may be asked whether if the female parts highl susceptible to cancer did not exist, or existed in a condition unaffected by sexual life, the same women would not succumb to cancer elsewhere. This question is too recondite to be answered positively but it may be stated that, in general, women succumb to cancer of the stomach and liver, and of other regions of which statistics are given, with about the frequency of men. Exceptions are the buccal cavity and skin, explained by greater frequency of irritation by smoking and by greater mechanic and thermic exposures, respectively. These groups are not large enough to affect the statistics to any great degree. Moreover, the general consistency of the net percentages after deducting sexual structures, especially in regard to the diminishing mortality due to exhaustion of susceptible material, is suggestive. It seems warrantable, therefore, that the high incidence of women to cancer of the breast and genitals, is really due to local predisposing and even determining causes and is not a vicarious localization of cancer in general.

Can any deductions be drawn from statistics as to the essential nature of cancer, particularly as to its infectiousness. In spite of a strong inclination to ascribe cancer to some germ (not necessarily a bacterium), which inclination is justified by analogy to granulomata, it must be admitted that the statistic evidence is rather against this theory. We may, of course, exclude anything approaching frank contagion, either analogous to air-borne infections to which most persons are susceptible or to a venereal infection. In the former case, we should expect a much earlier incidence, even if not more general, a more even distribution between the sexes, a steady fall as susceptible material was exhausted, and at least an appreciable influence on genital cancer due to prevalent aseptic precautions during pregnancy and labor, not to mention the improbability of genital infection from air-borne virus. In the latter case, we should expect some approach to the same relative frequency of genital cancer in the two sexes. The clinical lack of evidence of direct communication of cancer is also noteworthy. Yet, with all allowance for predisposition by early senility of epithelial structures, mechanic and other irritations, these may act, as in other diseases, comparatively infrequently and requiring special conditions for successful implantation of microorganisms, merely to favor the localization of an infectious process. Light might be shed on this problem if statistics could be gathered as to genuine repetition of cancer. But in the first place, there are no statistics of this nature on a large scale, and individual case reports are rare. The writer has seen only one such case—cancer of the stomach ten years after removal of cancerous breast—in an experience of over 25 years. It is doubtful whether even 5 per cent. of cancers are cured. A later malignant infection within a few years would reasonably be ascribed to a latent metastasis. The difficulty of the statistic problem is, however, considerable.

Provided that all cancer cases were submitted to operation—or radiant or other treatment shown to be relatively efficient in producing a radical cure—about 850 cured cases (on an approximate 5 per cent. estimate of curability) could be collated in a year, between the ages of 30 and 59. It is impossible to estimate the average normal death rate of this number, but considering their age, the undermining of health by disease, and in most cases, by a serious operation, it is doubtful whether much over half would survive ten years, irrespective of cancer. According to the initial age, this group of, say, 400 or 500, would have an average susceptibility to cancer, barring the removal of the locus minoris resistentiæ, of about 10 per cent. If it were possible to collect accurate data of such a series from widely separated reporters, we should expect 40 or 50 cases of repeated incidence of cancer by the law of chance, providing we could eliminate the two factors of exhaustion of susceptibility, however explained, and the lessened expected incidence owing to the sacrifice of what has been shown in the past to be a vulnerable site; and, provided further, that we could eliminate the question of long latent metastasis, or persistence with latency, of part of the original tumor, it is obvious that in about 15 years a very satisfactory amount of statistical material could be gathered, except for the difficulties of securing proper collaboration. If a repetition of cancer occurred in a percentage of the survivors, notably, higher or lower than 10 per cent., conclusions of considerable value, though not absolute, could be drawn regarding immunity or predisposition to recurrence, and in connection with other data these would be significant as to the essential nature of cancer, though, of course, they would not settle the question of infectiousness, since an infection may either immunize, predispose or be neutral as to recurrence.

## EPIDEMIC ICTERUS.

By AUGUST STRAUCH, M.D.,

CHICAGO, ILL.

Epidemic and subepidemic occurrences of icterus catarrhalis have long been noted, and among children especially they have been observed more frequently than among adults. Usually the epidemics have been small, confined to a house, a school, a family, a street or prison, a small community or a small area of a town, and they have ceased after a short period, though sporadic cases may in large cities continue throughout the year. However, more extensive epidemics have been observed, especially among soldiers, as, for instance, during the Civil War, when the patients in the armies numbered 10,929 cases as the highest record, with forty fatalities, or during the Franco-German War of 1870-71, when 2.4 per cent. of the soldiers of the First Bavarian Division suffered from jaundice.

In some epidemics adults exclusively, in others both adults and children, and in others children only were the victims. (Children's epidemics of Kramer, Rankin.) The greater number of records of epidemics among children are from England, Russia, Germany, Sweden, and France. Rehn reports 31 children and 8 adults, 1868, at Hanau, in Germany; Rasmussen, 73 cases in Denmark (48 children), and Meinert established the fact that from time to time there occur epidemics of jaundice in the population of Saxony. Kissel in an interesting publication reported 96 children, with 6 cases of death, in Moscow; Flesch 36 cases in Budapest; Nicolaysen 123 cases, with 50 children, in Christiania, 1901-1902; Ewer 115 cases in Berlin, 1904, and the *British Medical Journal* of 1904 contains not less than 10 reports of small epidemics of jaundice.

House, or family epidemics, also are as mentioned above, repeatedly recorded, and we find among English publications especially the statement, that wherever one child is affected by catarrhal jaundice other members of the family as a rule become affected, and occasionally all the children in the house may suffer. Aside from the record-breaking epidemics of the Civil War we find in the literature of this country only occasional references to epidemic jaundice, especially in the Northern States. During the last few years D. P. Dixon reports an epidemic (1907) in Talladaga of 200 or more cases with 25 children and 8 infants. Leslie saw in and about Andover (Maine) 135 cases of epidemic icterus within 6 months. Collins reports a local epidemic in Austin (Minnesota) of about 200 cases, the youngest 10 months old, during October and November, 1910, and he mentions local epidemics at Lake Wilson and Cambridge in the same State. Reports of house epidemics are published by Barker and Staden on 6 cases in the Baltimore City jail and by Robertson on six children in Onancock, Va.

The disease begins generally with loss of appetite, headache, pain in the limbs, nausea, vomiting, epigastric pain, lassitude and often fever. From one to three or four days later icterus of the scleræ and the skin sets in; the urine contains bile pigment, the stools may be diarrheic, constipated, or of normal consistency; as a rule they are clay colored, sometimes acholic or entirely normal; the liver and spleen are often enlarged and painful upon pressure. In some epidemics tonsilitis or bronchitis was a common symptom. As a rule, the duration of the disease is short, a few days to three weeks; the prognosis generally good, though the patient may get much emaciated and anemic; some epidemics, however, present more serious features and apparently slight cases may become grave and occasionally may end fatally (icterus malignus, Weil's disease, acute yellow atrophy of the liver). Meinert for instance saw among 518 patients 13 cases of exitus *letalis* of which two presented the picture of acute yellow atrophy of the liver.

I am induced to make these remarks and bring together these data as the result of the observation of jaundice in a family, affecting the four children consecutively within three to four weeks, the family residing in Irving Park, a suburb of Chicago.

Case I.—I saw the first patient, a girl six years old, on November 10, after she had been sick for about a week. Repeated vomiting, diarrhea, clay-colored stools, colic pain, loss of appetite, high fever, very intense jaundice. Liver was enlarged and painful upon pressure. Child remained only a few days in bed.

Case II.—A four-year-old boy became sick on November 30 with attacks of abdominal pain. No vomiting, no diarrhea, but stools soon became clay colored, the skin and scleræ icteric, and the urine brown. On December 5 icterus moderate; on December 7 icterus had disappeared; scleræ were white. No appetite; peevishness and lassitude persisted throughout those days, but the child was never confined to bed.

Case III.—Boy, thirteen years of age, became sick on December 1 with nausea, vomiting, colic pain, malaise; he felt very sick. On December 2 no fever; colic pain, vomiting repeatedly, constipation. After Carlsbad salt a few liquid, brown dejections. December 3, scleral icterus, slight fever, nausea, dejections liquid, brown colored. Boy feels very sick. December

7, liver enlarged, painful upon pressure, abdomen painful upon pressure, no enlargement of spleen; very intense icterus of sclerae and skin; no vomiting, no nausea, no appetite; urine brown colored. The boy was for about three weeks bedridden; the scleral icterus present for more than four weeks. Considerable emaciation.

Case IV.—Girl, 10½ years old, became sick on December 4 with vomiting, epigastric pain and fever; stool normal. On December 5, colic, nausea, vomiting, scleral icterus, no fever, pulse 72. On December 7, liver and spleen somewhat enlarged, painful upon pressure. Icterus of skin very marked; flatus; no malaise. Within the next week the symptoms disappeared; liver and spleen slowly decreased in size to the normal. The child was in bed for the first few days.

Upon investigation I found this fact: That about the same time, at least in one family, living only two blocks distant from the first family, all eight children became affected by jaundice. Contact among the children of the two families was very improbable. The character of the disease in the cases observed by me was mild, with the exception of the third patient, in whom it was rather severe. In one child there was moderate bradycardia, an uncommon feature in childhood, especially in the very young. (Henoch, Kissel.) The fact that the onset of the symptoms in each child did not occur at once, but successively, during a few weeks, rendered acute indigestion due to an error of diet or acute food poisoning improbable, and the anamnesis substantiated this view. The disease occurred in November, and in the beginning of December, when the weather was cool and damp. It is a notable fact, established from the study of the various epidemics, that fall and winter are the most common seasons for the occurrence of epidemic icterus, and not the summer, when the greater prevalence of acute and chronic gastrointestinal disturbances would lead us to expect a more frequent participation of the ductus choledochus in the catarrhal process of the duodenum. This fact and also that icterus is seen very rarely in the ages when errors of diet and gastrointestinal diseases with involvement of the duodenum are most common, to wit, in infancy, renders unsatisfactory the theory, that epidemic jaundice and perhaps also sporadic icterus catarrhalis (vulgaris) are caused simply by the spreading of an ordinary gastroduodenal catarrh to the ductus choledochus with resultant mechanical obstruction. Even in the adult jaundice is rare compared to the great frequency of common gastrointestinal catarrh from indigestion, errors of diet, alcoholic excesses, acute food poisoning, or some other factor. The origin seems rather to be due to a specific infectious agent, and this view is gaining adherents more and more. However, here arises the difficult problem of the pathogenesis of this icterus. It is most probable that the specific agents call forth a catarrh of the ductus choledochus and of the finer ramifications of the bile ducts, causing a more or less marked mechanical obstruction to the flow of the bile, with the stomach and intestinal tract—perhaps only the duodenum—participating in various degrees. How far toxemia and hemolytic causes or a disturbance of the function of the liver cells by bacterial toxins, that are produced in the intestines and carried through the portal vein into the liver, are responsible, causing paracholia and acachectic icterus, is an open question. The epidemic occurrence of "icterus catarrhalis" and the subsequent immunity mentioned by some authors speak also in favor of a specific infection.

A few epidemics have been observed simultaneously with epidemics of typhoid fever (M. Stoos) or in connection with influenza, as for instance in the epidemics recorded by Meissner, Young, Calvert, and Meinert in Dresden. A few epidemics followed revaccination with humanized vaccine lymph (Luermann, Jehn) so that a transmission of the infectious agent through vaccination was thought of. In other cases drinking water (Dixon, Collins) foodstuffs and milk were considered the carriers of the virus, but in the majority of cases no clue pointing to any etiological factor or factors could be found.

The bacteriological investigations so far have yielded no definite results. The demonstration by Jaeger and Banti of bacilli of the proteus group in a series of cases of icterus infectiosus gravis (Weil's disease) (and levis) throw some light upon the etiology; but it remains to be decided, whether or not other microorganisms as for instance colon bacilli are active in the majority of the cases of icterus levis, injuring the bile ducts and the liver directly by their invasion or their toxins.

**Secondary Colipyelitis.**—Bloch states that this affection is a not infrequent complication of gonorrhea, and may be divided into a pyelitic, a nephrotic, and a pyelonephritic form. The first two may be latent in the acute stage, so that the diagnosis may only be made when the chronic stage is reached. Coli infection proceeds as a rule from the bladder upward and by the lymphatic route. The appearance of the affection is favored by certain factors which facilitate the ascent of the coli bacilli. These comprise: temporary overpressure in the bladder, called forth by strongly irritating irrigations; temporary slowing of the urine stream, caused by slight impediments in the ureters, and finally mechanical irritation in strong hyperemia of the urogenital systems. In the acute stage of pyelonephritis internal treatment is indicated, while in the other two forms local therapy alone is indicated in this stage. If the secondary coli pyelitis is recognized at the right moment and treated complete recovery will result in the great majority of cases. In the pyelonephritic form parenthymatous nephritis may develop. —*Deutsche medizinische Wochenschrift.*

## THE PROBLEM OF PERNICIOUS ANEMIA.

ONE of the most vexing problems in modern clinical medicine is that which is concerned with the origin of pernicious anemia. In 1878 Eichhorst differentiated two types of this disease, namely, a protopathic or cryptogenic form and a deuteropathic or symptomatic form. This division is the one which is substantially recognized at the present day. Pappenheim describes a blood picture in pernicious anemia which is sharply distinguished from that of genuine Biermer's disease. Türk describes a type of pernicious anemia with known factors and another type in which the factors are unknown. O. Roth has had the opportunity of observing in Eichhorst's clinic in Zürich a number of cases, from the study of which he has been able to draw a few important conclusions with reference to this subject. His results are reported in the *Zeitschrift für klinische Medizin*, Vol. 79, Nos. 3-4.

Among these cases there were two occurring in brothers in whom the disease began at the ages of 45 and 59 years, respectively. In both patients the disease was of the cryptogenic type, the genuine Biermer's disease. The question arises whether both cases represent a mere coincidence or whether they indicate a familial tendency to this disease. As regards familial occurrence, other cases have been reported, for instance, by Weill and by Wilson but particularly by Schaumann, who observed the multiple occurrence of pernicious anemia in as many as eight families. In some of his cases he was dealing with a bothriocephalus anemia, in some with a cryptogenic anemia, and in others with both types. Another of Roth's cases occurred in a 62-year-old male, who also suffered from cirrhosis of the liver. This condition was confirmed at autopsy. The question arises whether one is dealing in this instance with a causative relationship between both conditions or with a mere coincidence. The author believes that cirrhosis of the liver may play a rôle in the production of some cases of pernicious anemia.

Another one of his cases was that of a woman aged 48 years in whom examination of the blood showed a typical pernicious anemia and who presented a marked rise of temperature that lasted for several weeks. At autopsy there was found a nodular tuberculosis of the spleen, a miliary tuberculosis of the liver, and a widespread caseous glandular tuberculosis which was most marked in the tracheobronchial lymph nodes. The same problem arises in this case as to whether there was any relationship between the tuberculosis and the pronounced anemia which had every earmark of a symptomatic pernicious anemia. There can be no question that tuberculosis may give rise to severe anemia, but it is probable that a hemolytic anemia is not caused by tuberculosis without the presence of some other factor. Two other cases studied by the author occurred in patients 71 and 72 years old, respectively. Both of these were undoubtedly cases of pernicious anemia associated with marked cachexia, emaciation, and muscular atrophy, all of which gave one the impression of some underlying malignant cause. It occurred to Roth that possibly in these cases the blood condition might be the result of senile changes. The fifth phase of pernicious anemia in conjunction wtih other conditions was noted in the case of a gravid woman who also presented signs of pernicious anemia.

In summing up the results of his studies of the above cases, Roth concludes that one may recognize a number of factors that may play a causative rôle in pernicious anemia. The familial occurrence would speak in favor of an individual predisposition. Tuberculosis of the lymph glands and spleen, cirrhosis of the liver, and senility would give rise to a symptomatic pernicious anemia. It must be admitted that these conclusions are of extreme interest, but nothing new has been added by Roth to what is already known about pernicious anemia, whose real origin is still deeply veiled in obscurity.

## PNEUMONIC HEMIPLEGIAS.

OCCASIONALLY in the course of an attack of pneumonia, a cerebral accident will occur. As a matter of fact, such accidents are not of very rare occurrence, and in the *American Journal of the Medical Sciences* for February, 1914, Dr. Charles F. Withington discusses the matter at some length. He points out that pneumonic hemiplegias may be divided into two classes: (1) Those caused by gross anatomical lesions, such as meningitis of pneumococcic origin, thrombosis, embolism, softening, abscess, etc. (2) A group to which exclusive attention is given in Withington's article. The cases in this group occur generally in young and vigorous people and their prognosis is relatively much better than that of the first group. Four principal explanations of the hemiplegias of this group have been offered: (1) Encephalitis, of the Strümpel type. Hoppe-Seiler gives pneumonia as one of the rarer causes of encephalitis and seeing that the relation of the latter condition to influenza is now generally recognized, it is possible that it is to pneumonias of influenzal origin that encephalitis has a particular relation. Comby has shown that encephalitis is related to other infections like pertussis, enteritis, mumps, typhoid fever, etc. Mollard and Dufort describe the case of a man taken on the seventh day of pneumonia with marked cerebral symptoms, but giving on lumbar puncture a clear fluid. He died the following day, when an encephalitis was found. (2) A second assigned cause is hysteria.

(3) Circulating organisms. If pneumonia is, as is now believed, a septicemia, there is little doubt that its organism may be carried in the blood stream to the grain, but as Withington points out it is somewhat difficult to understand how circulating organisms should so mass themselves in the brain as to produce hemiplegia. (4) Circulating toxins. The same objection, however, applies to circulating toxins as to circulating organisms. Stephan in 1889 attributed the symptoms to a vasomotor ischemia caused by ptomains in the blood which set up a vascular reflex analogous to what may occur in uremia.

Even in conditions producing cerebral edema, it seems reasonable, as suggested by Robert T. Edes, that hemiplegia might be caused if the posture of the patient made an excess of the fluid gravitate to one side of the brain. Of the above mentioned theories of the production of pneumonic hemiplegia, Withington is of the opinion that more than one is correct.

Several cases of this accident in pneumonia are given by the author, who also draws attention to the fact that the mortality of many of these toxic forms of pneumonia with hemiplegia does not seem to be greatly increased by the supervention of the cerebral symptoms. It is likewise pointed out that the importance of the phenomena referred to is great from the prognostic point of view and seems to be hardly appreciated.

## RADIUM THERAPY.

One of the most recent discussions on radium therapy was held before the Medical Society of London on March 9. Major A. E. Hayward Pinch opened the discussion and gave a fairly exhaustive review of the present position of radium as a therapeutic agent. With regard to the radium treatment of malignant disease, he affirmed that the proper treatment of such disease which was operable was by operation, and he did not use the word "cure" for the results of radium treatment in relation to new growths. In carcinoma of the tongue and mouth there had been some encouraging results by the use of small and powerful tubes. Carcinoma of the esophagus had been temporarily benefited but Pinch had not seen a case of arrest of the growth through the agency of radium. The annular type of carcinoma of the rectum was influenced more than the plaque variety of growth. Some very good results had followed treatment of carcinoma of the bladder, and he had seen no results equal to those obtained by radium, operation excepted, in carcinoma of the uterus. The neoplasms which responded best of all were the sarcomata, particularly those in the nasopharynx, and the lymphosarcomata. Melanotic sarcoma was best left untreated by radium. In lymphadenoma great and rapid temporary improvement had followed such treatment. Pinch insisted that it was incumbent upon all to exercise the greatest caution in the publication of their results, and more especially of statements which might afford an opportunity for distortion by the lay press. The effects of garbled announcements in the daily papers were often most tragic, and the amount of mental distress caused to patients and their relatives when they were informed of the true position of affairs was incalculable. He could find it in his heart to wish that all workers with radium might be pledged to a policy of silence for two years, and although this was impossible, he could, at any rate, urge the deletion of the word "cure" from their vocabulary when speaking of the radium treatment of malignant disease. No one could deny that we did possess in radium a therapeutic agent of great power, but how powerful it would prove to be was still a matter for conjecture.

Most authorities on radium therapy, if there may be said to be authorities regarding the action of a therapeutic remedy concerning which so much has yet to be learned, confess that its limitations are great and disclaim for it curative properties, at any rate, in the treatment of malignant disease. Exaggerated assertions as to the remedial or curative properties of radium are not only unjustifiable but are productive of an immense amount of harm. Unguarded statements respecting medical treatment of any description are seized upon by the lay press and retailed to the public in a form often quite different from that in which it was first issued. Publicity used with discretion is for the good of all, but unreliable accounts of medical matters are distinctly injurious both to the medical profession and to lay readers.

## A More Hopeful Outlook in the Philippines.

The Philippine Legislature adjourned on the last day of February and will not convene again until October, and there is great rejoicing thereat in Manila among all but the native politicians and the most ignorant of the population. Not the least of the jubilation is due to the fact that the solons failed in their endeavor to have the Director of Health removed and a subservient Council of Health composed chiefly, if not entirely, of Filipinos, appointed in his stead, as well as to take from him the control of the Philippine General Hospital. The post of Director of Health in Manila is not an enviable one in these days. He is subject to almost incessant attack from the native press because of his efforts to prevent the spread of cholera and plague which ever menace the city, he has had to accept a Filipino assistant who openly boasts that the natives will soon be in complete control of sanitary affairs, and he has been indicted, on the strength of some forty trumpery charges of malfeasance brought by a legislative committee, because he did not heed the ignorant protests of natives who were put to temporary inconvenience by his efforts to save their lives. That the enemies of sanitation have not succeeded in their efforts to oust Dr. Heiser is due largely to the loyal support of Governor-General Burton Harrison, who has learned much since his arrival in Manila and is brave enough to admit it. Mr. Harrison several times has assumed full responsibility for unpopular orders which Dr. Heiser was forced to issue and which without this support of the Governor-General might have failed of execution. It is most satisfactory and comforting to know that the filipinization of the island government will not, for the present at least, involve serious crippling of the work of sanitation.

### Abuses of the Diagnostic Laboratory.

Within the past few years there have sprung up in many of the larger cities of the country a number of diagnostic laboratories in which chemical and microscopical examinations of the body fluids and excreta are made. The charges for these examinations are not large, and the service which the laboratories have rendered to the busy practitioner has been considerable. There is, however, one phase of this work that calls for comment. Many patients are in the habit of bringing specimens, usually of urine, to the laboratory without the knowledge of their physician and of receiving reports which they believe themselves competent to interpret. This is particularly to be observed in the case of many diabetics who are practically guiding their own treatment according to the laboratory report. The danger of this practice requires little comment. The diabetic may congratulate himself that he is on the road to recovery when he reads in the report that his urine contains little or no sugar, when in reality he may be on the verge of coma. The sufferer from chronic nephritis may be deluded by the report that his urine is free from albumin at a time when an attack of uremia is imminent. Of course, the individual who essays the task of treating his own ailment is not likely to be guided by the advice of those who are wiser than he. Nevertheless it is the physician's duty to warn his patients against the danger of self treatment. The physician who avails himself of the services of the so-called diagnostic laboratories should insist upon the maintenance of an absolutely confidential relationship between himself and the laboratory. Under no circumstance should the report of the analysis be entrusted to the patient.

### The Pancreas Toxicosis.

The subject of Abderhalden's reaction of proteolytic disintegration—caused by the entrance into the blood of organic substances of a more or less alien character, which are disposed of through digestion by enzymes, either pre-existent in the blood or generated for the occasion—has naturally developed a new pathology. Let us suppose that the pancreas becomes the seat of an acute inflammation and rapid necrosis. Then the entrance into the blood of the products of autolysis of the gland causes phenomena which are closely associated with the symptoms which follow the abolition of its function. Severe as are the latter, they cannot be compared with the results of absorption of toxic material, which naturally occurs at an earlier period. Von Bergmann and Strauch have for many years studied pancreatic autolysis in necrosis following acute pancreatitis and have found that fatal poisoning rapidly occurs in certain cases. In a paper read before the Biological Section of the Medical Union of Hamburg on Dec. 16, 1913 (*Muenchener medizinische Wochenschrift*, March 3), they announce the results of attempts to study the affection with Abderhalden's reaction, especially when only suspicion exists as to a latent state (in sufficiently obvious cases such a resource is not indicated). The authors do no more than state that a positive Abderhalden is of much value in such cases. In a long discussion on Abderhalden's reaction in general, which took place afterwards, no mention whatever was made of the pancreas, so that the authors are, no doubt, pioneers in this subject.

### Tuberculin Treatment of Spina Ventosa.

The successful use of tuberculin in local conditions of doubtful origin has been demonstrated again and again. Whether this result indicates the tuberculous nature of the lesion, or whether a tuberculin general reaction, with fever, has simply caused the disappearance of some long-standing condition, is beside the mark. We are only interested at present in the possibility of curing spina ventosa with tuberculin. At a meeting of the Hufeland Society of Berlin, last January (*Berliner klinische Wochenschrift*, March 9, 1914), Dönitz presented a paper on this subject. Under *x*-ray control both destruction and atrophy of bone, as well as new formation, were in evidence; and all lesions yielded in the main to old tuberculin. This medication is specially indicated in lesions of the ribs, sternum, vertebræ, joints, etc. Karewski expressed the view that tuberculin improves local conditions only indirectly, by raising the general resistance of the organism. He sees no evidence that tuberculin *per se* exerts a specific influence over spina ventosa, the successful management of which can go ahead under the old regimen. Closing the discussion Dönitz admitted that he regarded tuberculine rather as a stimulant than a specific.

## News of the Week.

**Deaths in New York.**—During the week ending April 4 there occurred in New York City 1,612 deaths, giving a death rate of 15.06 per 1,000 of population, as compared with 1,512 deaths and a rate of 14.68 for the corresponding week of 1913.

**The Plague in Havana.**—There have been five cases of plague in Havana during the present outbreak. In order to put an end to it Dr. Juan Guiteras, the Director of Sanitation, has ordered that sixteen blocks in the infected portion of the city be closed for several days while the rats in the district are being killed.

**Affiliation of College and Hospital.**—Through the trustees of Columbia University announcement was made last week that the managers of the Presbyterian Hospital, New York, had reorganized the administration of the scientific and therapeutic work at the hospital so as to provide for single responsibility for both medical and surgical services. Dr. Theodore C. Janeway, Bard professor of the practice of medicine at the College of Physicians and Surgeons, has been designated medical director of the hospital, and Dr. George E. Brewer, professor of surgery at the college, has been designated surgical director. Dr. William G. MacCallum, professor of pathology at the college, has been appointed pathologist to the hospital.

**Hospital Overcrowding.**—A night inspection of the hospital quarters on Blackwell's Island made by the Mayor of New York and several members of the Board of Estimate on April 7, will lead, it is hoped, to a great improvement of the accommodations. Overcrowding, poor food, and shortage of nurses were among the defects pointed out. At the Metropolitan Hospital, where the worst conditions exist, it was found that 1,070 tuberculous patients were being cared for, although the hospital has accommodations for only 800. In the sixteen glass shacks put up for the fresh-air treatment of the tuberculous, 197 patients were found sleeping in quarters designed to hold only 67, and the ventilation of the rooms was insufferable. Through all

the hospitals on the Island it has for some time past been found necessary to put cots in the corridors and even to make up pallets on the floors of the wards. After the inspection the members of the Board of Estimate announced themselves ready to make the necessary appropriations to remedy the congested conditions.

**Aviation Deaths.**—During the first three months of 1914, 38 men in all parts of the world lost their lives through the failure of their machines or the uncertainty of air currents, five of these deaths occurring in the United States. Since the death, in 1908, of the first victim of aviation, 462 men have been killed as the result of accidents while in the air.

**International Surgical Congress.**—Dr. W. W. Keen of Philadelphia has been elected president of the next Congress of the International Surgical Association to be held in Paris at the end of September, 1917. The officers of the association, re-elected at the meeting held this week in New York, are: *President*, Dr. Willems of Ghent; *Secretary*, Dr. Mayer of Brussels; *Treasurer*, Dr. Lorthioir of Brussels.

**The American Surgical Association.**—At the annual meeting of this association, held last week in this city, the following officers were elected: *President*, Dr. George E. Armstrong, Montreal, Canada; *Vice-Presidents*, Dr. Lewis S. Pilcher, Brooklyn, and Dr. Frank E. Bunts, Cleveland; *Secretary*, Dr. Robert G. Leconte, Philadelphia; *Treasurer*, Dr. Charles L. Gibson, New York; *Recorder*, Dr. Archibald MacLaren, St. Paul; *Members of Council*, Dr. W. J. Mayo, Rochester, Minn., Dr. A. G. Gerster, New York, and Dr. Charles A. Powers, Denver, Col. The next meeting will be held in Rochester, Minn.

**Personals.**—Dr. Milton Schnaie, first assistant physician at the Montefiore Country Sanitarium for Consumptives, Bedford Hills, N. Y., has resigned to become medical director of the new Jewish Home for Chronic Invalids and Consumptives at St. Louis, Mo., which position he will assume on May 1.

**Control of Cancer.**—A public meeting of the American Society for the Control of Cancer was held at the New York Academy of Medicine on April 10, Dr. Clement C. Cleveland, vice-president of the society, presiding. After Dr. Cleveland had spoken on the needs of the society, which has for its objects: "To disseminate knowledge concerning the symptoms, diagnosis, treatment, and prevention of cancer, to investigate the conditions under which cancer is found, and to compile statistics in regard thereto," Dr. William J. Mayo of Rochester, Minn., made some introductory remarks, and addresses were made by Mr. Frederick L. Hoffman of the Prudential Insurance Company on "The Statistical Evidence of an Increasing Liability to Cancer," by Dr. Francis Carter Wood, director of Cancer Research, Columbia University, on "The Nature of Cancer and Its Cure," and by Dr. J. Collins Warren, chairman of the Harvard Cancer Commission, on "The Control of Cancer from the Point of View of the Cancer Commission of Harvard University."

**Smallpox in New York.**—The discovery of two additional cases of smallpox in New York last week, making a total of six cases reported within a month, has caused the Commissioner of Health to issue a strong appeal to all citizens to protect themselves by submitting to prompt vaccination against the disease.

**Typhus Patient at Ellis Island.**—A patient suffering from typhus fever, who had reached Ellis Island from the steamship *Cameronia* of the Anchor line on April 7, was discovered while the immigrants were being inspected at the Island and was promptly sent into quarantine at Swinburne Island. The other steerage passengers from the same ship were quarantined at Hoffman Island, and arrangements were made for the thorough disinfection of the ship. Several passengers with the disease have lately been brought into port, but this is the first case known to have passed the quarantine officials.

**Doctors Leave Nassau.**—Because of some disagreement as to the proper conduct of hospital affairs, the three physicians forming the house staff of the Nassau Hospital, Mineola, N. Y., handed in their resignations on April 8, and immediately left the hospital.

**Scarlet Fever in Richmond Borough.**—Scarlet fever has been quite prevalent in Dongan Hills, Staten Island, N. Y., since the end of last January. During February 13 cases occurred; during March, 12 cases, and during the first week of the present month 4 cases were reported. The responsibility for the increased number of cases of this disease probably rests with the parents of certain children who failed to summon a physician during their children's illness, and permitted the children to return to school while they were still in an infectious condition and capable of spreading the disease to others. Some time later the cases were recognized as scarlet fever by a physician of the Department of Health and the children were excluded from school; but the damage had already been done. The Health Department now has the situation well in hand and it is probable that few additional cases will occur.

**Gifts to Charities.**—By the will of the late William P. Sandford of Brooklyn, N. Y., the sum of $5,000 is left to the Methodist Episcopal Hospital of that city.

The William W. Backus Hospital of Norwich, Conn., receives $15,000 by the will of the late John Eccles of Norwich.

The Exeter Cottage Hospital of Exeter, N. H., has received a bequest of $10,000 from the estate of the late Mrs. Elizabeth S. Hall.

**Antivaccination Bill.**—The Massachusetts State Senate on April 10 passed an antivaccination bill which provides that any person who has reached the age at which attendance at school is permitted or required, and who presents a written statement from a parent or guardian, or by himself, if twenty-one years old, which declares that such parent or guardian or person is opposed to vaccination, shall not, as a condition precedent to admission to the public schools, be required to submit to vaccination, except at the time of a threatened or actual outbreak of smallpox, when the school board shall temporarily debar such person from the schools.

**Medical Society Elections.**—New London County (Conn.) Medical Society. Annual meeting at New London on April 2. Officers elected: *President*, Dr. Anthony Peck, Norwich; *Vice-President*, Dr. Edmund P. Douglass, Groton; *Clerk*, Dr. Leone F. La Pièrre, Norwich; *Councilor*, Dr. Patrick J. Cassidy, Norwich.

Lafayette Parish (La.) Medical Association: Annual meeting at Lafayette on March 27. Officers elected: *President*, Dr. John Leon Chiasson, Scott; *Vice-President*, Dr. George R. DeLaureal, Broussard; *Secretary-Treasurer*, Dr. Merrick E. Saucier, Marksville.

**The Late Dr. Le Fevre.**—At a meeting of the Medical Board of the Beth Israel Hospital the following resolutions were adopted:

*Whereas*, The Medical Board of the Beth Israel Hospital has learned with deep sorrow of the death of Dr. Egbert Le Fevre, consultant physician to the hospital for the past twenty years, and

*Whereas*, Dr. Egbert Le Fevre was a man of noble character, sterling integrity and of high medical attainments, and was always ready and willing to devote his very valuable services to the welfare of the patients and by his uniformly kind and courteous treatment of the members of the Visiting Staff, as well as the patients, has gained for himself the sincere appreciation of the Medical Board and the gratitude of the sick poor; be it

*Resolved*, That as a mark of the esteem in which Dr. Le Fevre was held by the Medical Board and in appreciation of his services to the Beth Israel Hospital, the above resolutions be spread on the minutes of the Medical Board and that a copy be sent to the family and be published in the medical press.

L. J. Ladinski, M. D., *Chairman*,
D. Robinsohn, M.D.,
A. A. Himowich, M. D.,
*Committee on Resolutions.*

**Obituary Notes.**—Dr. Charles F. Lauer, of Brooklyn, N. Y., a graduate of the New York Homeopathic Medical College and Hospital in 1863, and a member of the New York State Homeopathic Medical Society, died at his home on April 9, aged 74 years.

Dr. Thomas Lee of Camden, N. J., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1876, died at his home on March 24, aged 72 years.

Dr. William E. Easter of Hamburg, Ark., a graduate of the Western Reserve University, Medical Department, Cleveland, O., in 1853, died at his home on March 23, aged 82 years.

Dr. Elihu Britton Silvers of Rahway, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1852, a member of the Medical Society of New Jersey, and the Union County Medical Society, of which he was a former president, and formerly superintendent of schools of Rahway and a member of the Board of Education, died at his home from heart disease on April 2, aged 85 years.

Dr. Charles Emery Rowell of Stamford, Conn., a graduate of the New York Homeopathic Medical College and Hospital in 1875, formerly mayor of Stamford, and a member of the Board of Health, died at his home on March 28, aged 64 years.

Dr. Gustavus Pierrepont Davis of Hartford, Conn., a graduate of Yale University in 1866 and of the College of Physicians and Surgeons, New York, in 1869, a member of the Connecticut State and Hartford County Medical Societies, and one of the founders of the Hartford Free Dispensary, died at his home on April 1, aged 69 years.

Dr. George W. Brumley of Biggers, Ark., died at his home on March 23, aged 69 years.

Dr. Marvin M. Johnson of Waycross, Ga., a graduate of the Medical College of Georgia, Augusta, in 1902, a member of the Medical Association of Georgia, and president of the Ware County Medical Society, died suddenly in his office from heart disease on March 21, aged 34 years.

Dr. Thomas W. Stumm of St. Paul, Minn., a graduate of the Rush Medical College, Chicago, in 1901, a member of the American Medical Association, the Minnesota State Medical Association, the Ramsey County Medical Society, of which he was a former president, and the Academy of Medicine of St. Paul, and physician to St. Luke's, St. Joseph's, and the City Hospitals, died suddenly in Vienna, where he was pursuing his studies, on March 20, aged 42 years.

Dr. Levi Hall of Minneapolis, Minn., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1882, died at his home on March 22, aged 81 years.

Dr. A. O. Hardenstein of Vicksburg, Miss., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1889, died in the Presbyterian Hospital, New Orleans, after a short illness, on March 21.

Dr. Leander F. Murray of Holden, Mo., a graduate of the Louisville Medical College, Ky., in 1876, and a member of the Missouri State and Johnson County Medical Associations, died at his home after a long illness, on March 21, aged 67 years.

Dr. S. H. C. Bixler of Greenville, Pa., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1870, and a veteran of the Civil War, died at his home on March 28, aged 69 years.

Dr. Alvin Isaac Miller of Harrisburg, Pa., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1872, died at his home on March 26, aged 64 years.

Dr. Oliver H. Sterner of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1889, died at his home from pneumonia on March 27, aged 55 years.

Dr. John Thomas Shepherd of Chattanooga, Tenn., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1874, formerly physician to the Hamilton County Hospital, died suddenly at his home on March 22, aged 66 years.

Dr. Horace E. Seastrunk of Orange, Texas, a graduate of the Barnes Medical College, St. Louis, in 1896, died at his home after a long illness, on March 25, aged 39 years.

Dr. Martin Hagen of Virginia, Wis., a graduate of the Chicago College of Medicine and Surgery in 1908, and a member of the American Medical Association, the State Medical Society of Wisconsin, and the Crawford County Medical Society, was instantly killed by being thrown from his horse on March 23, aged 42 years.

Dr. Philip M. Fitzsimons, of Cambridge, Mass., a graduate of the University of Vermont College of Medicine, Burlington, in 1892, and a member of the Massachusetts and Middlesex District Medical Societies, and formerly a member of the Cambridge School Board and Medical inspector of schools, died at his home after a long illness, on April 4, aged 56 years.

Dr. William Stockton Wilson of Newark, N. J., a graduate of the Jefferson Medical College, Philadelphia, in 1861, for three years during the Civil War a surgeon in the United States Army, and a member of the Medical Society of New Jersey and the Essex County Medical Society, died at his home on April 10, aged 75 years.

Dr. Thomas A. Rex of Los Angeles, Cal., and formerly of Philadelphia, a graduate of the Georgetown University School of Medicine, Washington, in 1865, an assistant surgeon in the United States Army during the Civil War, and a member of the Medical Society of the State of Pennsylvania, died at his home on April 1, aged 76 years.

# Correspondence.

## THE FRIEDMANN SERUM AND THE SOCIETY OF GERMAN SANATORIUM PHYSICIANS.

To the Editor of the Medical Record:

Sir:—A sensational statement appeared last month in some of the New York newspapers that on the occasion of the annual meeting of the Association of German Sanatorium Physicians on February 28, 120 of these physicians had carefully investigated the results of Friedmann's work. It was reported that 40,000 cases had been treated with Friedmann's serum and that the successes had been simply phenomenal. It was furthermore stated that Dr. Friedrich Franz Friedmann had been the guest of honor at a banquet given by the sanatorium physicians and that he had been effusively thanked by Privy-Councillor Professor Dr. Pannwitz for his work, in the name of the sanatorium physicians present. Finally, it was said in the newspaper report that Dr. Friedmann had made the statement to an American press representative that Professor Ehrlich had expressed the opinion that the Friedmann serum was absolutely harmless.

In a communication received by the undersigned, bearing the signatures of the president, Dr. O. Pischinger, the vice-president, Dr. J. Ritter, and the secretary, Dr. Schellenberg, of the Association of Sanatorium Physicians of Germany, Austria, and Switzerland, he was requested to enlighten the American medical profession concerning the incident connected with their visit to the Friedmann Institute in Berlin, and to give the facts the widest possible publicity, at least among medical men.

First of all, the officers of the association expressed their astonishment that the visit of the sanatorium physicians to the Friedmann Institute should have been used as a means of advertising Friedmann and his remedy abroad. Because of the reports of cures which constantly crept into the German medical and lay press and the demands for the remedy from many sanatorium patients, it was natural that the sanatorium physicians while visiting Berlin should wish to see for themselves what was going on in the Friedmann Institute. Thus they asked Friedmann to show them his cases and give them a talk on the indication for his remedy. About 60 of the 125 members of the association visited the Friedmann Institute on February 26 and 27, 1914. They distinctly stated that their visit was in no way to be considered a pilgrimage to pay homage to Friedmann for his discovery but rather an investigation to find out just how much truth there was in his claims. Many had already tried the remedy and had been disappointed, others were prejudiced, and it is for this reason that they wanted to examine critically into Friedmann's claims. It is absolutely untrue that a banquet was given to Dr. Friedmann. After the conclusion of the visit there was a confidential conference, without Dr. Friedmann, at which the members concluded to discuss the theme again next fall and in the meantime collect as much material as possible.

That the undersigned may not be accused of prejudice or misinterpretation, I wish to quote in German the most essential statements which were made as the result of the visit of the association to the Friedmann Institute:

"Wir waren uns darüber einig, dass die uns von Friedmann gezeigten Fälle klinisch recht schlecht beobachtet waren und im Allgemeinen keineswegs als 'Erfolge' angesehen werden konnten. Wir haben uns gewundert, dass uns keine ordnungsmässig geführte Kurve gezeigt wurde. Die Roentgenplatten, die man uns zum Beweis zeigte, bewiesen tatsächlich garnichts. Wir geben zu, dass einzelne Fälle allerdings einen gewissen Eindruck auf uns gemacht haben, *wobei wir uns aber auch darüber klar waren, dass solche Fälle auch ohne jede Behandlung und bei jeder Behandlung vorkommen können*, und das die Zahl dieser Fälle verhältnissmässig *viel* zu klein war, um ein günstiges Urteil über das Mittel abgeben zu können."

(We were of the unanimous opinion that the cases shown by Friedmann had been clinically very badly observed, and as a whole could not at all be considered as successes. We were astonished that no carefully recorded temperature and weight curves were shown. The *x*-ray plates which were shown to us as evidence of cures did not actually prove anything whatsoever. We will admit that some cases indeed made an impression upon us, but here we must also remember that such cases occur without any treatment or with any kind of treatment, and that the number of them was altogether too small to permit of a favorable judgment of the value of the remedy).

I have since received a letter from Geheimrat Prof. Dr. Pannwitz in which he substantiates what has been said in the official communication from Drs. Pischinger, Ritter, and Schellenberg. He particularly expresses his indignation at the use of his name in connection with a banquet which never took place. He declared the whole thing to be a newspaper invention.

Prof. Dr. L. Brauer, Director of the Eppendorfer Krankenhaus of Hamburg, who had also heard the American version of the sanatorium physicians' visit to the Friedmann Institute in Berlin, wrote me a letter full of indignation and said at the same time that he had tried Friedmann's remedy at the Eppendorfer Krankenhaus and the results had been unfavorable. He has reported these unfavorable results recently at the Balneological Congress and the Hamburger Aerzte Verein, and intends to publish more on the subject at an early date. He has since sent me the advance sheets of his forthcoming communication regarding Friedmann wherein he says: "The pulmonary cases treated in the Eppendorfer and Salemburg hospitals with Friedmann's method did not improve, but some of them without a shadow of doubt were rendered worse by the treatment. Five cases of bone and joint tuberculosis in children treated with the Friedmann serum by Dr. Trepler in the Salemburg institution were not influenced at all by the treatment and in one case, although the movement of the afflicted joint increased, the general condition of the lesions was rendered worse."

In paying a gratifying tribute to the earnest and unbiased work done with Friedmann's serum by American investigators, which likewise gave unfavorable results, Professor Brauer advised me, in the interest of the German medical profession, and especially in the interest of the unfortunate patients who naturally are inclined to accept such advertised endorsement as genuine, that it would be most desirable for the present status of the Friedmann remedy in Germany to be made clear to the American medical profession and the laity.

## THE METROSCOPE.

To the Editor of the Medical Record:

Sir:—If any of your readers can give me any information concerning an instrument called the metroscope it will be of much service to me.

Montgomery in his "Signs and Symptoms of Pregnancy," 1857 page 173, quotes from "Des Maladies propres aux Femmes," page 752, as follows: "In 1829 M. Nauche proposed for adoption a practice founded on a suggestion made by M. Maygrier in 1822, viz., that certain conditions of the gravid uterus might be ascertained by auscultation instituted per vaginam; for this purpose M. Nauche had constructed a modification of the stethoscope under the name of metroscope, one end of which was to be applied to the os uteri * * * the movements of the fetus might be recognized * * * long before the mother felt them herself, or ballottement could be accomplished."

Any information, comment, or criticism will be thankfully welcomed.

DOUGLAS H. STEWART, M.D.

128 WEST EIGHTY-SIXTH STREET, NEW YORK.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

BIOLOGY OF TUMORS—CONGRESS OF AMERICAN SURGEONS—WELCOME TO SURGEON-GENERAL GORGAS HIS LECTURE ON THE PANAMA CANAL—ARTERIOSCLEROSIS ETYMOLOGY—DOCTORS' WIVES—MEDICAL CYCLOPEDIA FOR FAMILY USE.

LONDON, March 27, 1914.

MR. MANSELL MOULLIN, consulting surgeon to the London Hospital, took for the subject of his Hunterian lecture at the College of Surgeons, "The Biology of Tumors." The underlying problem is not, he holds, the nature of the force which makes tumors grow, for growth is a property of all living tissues, but it can suddenly be interrupted at some spot when the force which controls growth and directs it toward development is removed leaving the tissues to simply increase and multiply in any direction. The nature of this force, he thought, may in some instances be traced to interference with chemical changes in the tissues. The causes of such interference would thus become factors in the production of tumors. This view was elaborated with great skill as to the different kinds of tumors which are to be regarded as buds that grow out of normal living tissues always developing along the same line as the stem but never attaining a higher stage. Consequently a natural classification would give three groups: First, those arising from the primitive organism, then those arising after it has become differentiated into germ and somatic cells. The bud or tumor growing from either of these cells reproduces more or less perfectly the arrangement of the previous cells. The lecturer spoke of the different varieties, and passed on to show that clinical classification is valueless. Whether a tumor is malignant or benign depends on the degree of maturity reached by the cell from which the bud branched off. If that parent cell had advanced so far as to have attained distinctive characteristics but not to have lost all power of reproduction, the bud would imitate it, growing slowly and pushing aside other structures, *e.g.* adenomata built of buds resembling the parent gland but never so perfect. On the other hand, if the parent stock is in the embryonic stage, composed of rapidly growing cells, such as spring up to replace older, worn out, or lost cells, the bud cells will be of the same embryonic type, multiplying rapidly and invading everything around. So cancer does not arise from tissues perfectly developed, but from cells engaged in repair and restoration.

Prof. Mansell Moullin said the assumption that cancer and sarcoma were essentially different from all other tumors was not supported by evidence, but that the cancer cell or the sarcoma cell, like the cells of all other tumors, was the descendant of a normal tissue cell, which in its earliest youth, while retaining all its primitive reproductive power, had suddenly assumed an individuality of its own and was no longer bound by the laws that control the growth and development of its host. Why a cell or group of cells should thus cease to develop and retain its power of growth and reproduction, giving birth in this way to another individual is the problem of the biology of tumors. The lecturer's suggested solution was that development being dependant, like growth, on certain chemical changes taking place in the living cell interference with them must produce corresponding effects. Development is the persisting succession of growth in one direction by a group of cells, generation after generation, leading to modification of chemical constitution and of structure. If the changes should be interrupted at some point, as for lack of some essential factor, or the intrusion of an unnecessary one, the special reaction concerned is brought to a standstill at whatever stage it may be. Development ceases but the power of reproducing may remain. Then growth goes on, a tumor resulting, reproducing the parent's structure at the stage at which it was at the moment of interruption. Other changes than chemical may also affect tissues, *e.g.* mechanical or the action of living organisms, and the lecturer cited some of these. When there is no interruption of the changes development continues.

We are "going straight ahead" with preparations for the reception of the Clinical Congress of American Surgeons in July. A committee meets at the Royal Society of Medicine and most of the hospitals will be ready to receive members during each day and in the evenings there will be addresses by surgeons from the provinces and abroad.

We have had Surgeon-General Gorgas staying here a few days on his return from South Africa, to which he went at the request of the Johannesburg Chamber of Mines to examine the sanitary conditions under which their workmen lived. He has had a warm welcome with the two colleagues, Dr. Darling and Major Noble, who accompanied him in his South African work. The three were entertained at dinner by the Medical Director-General and some eight officers, and a number of other compliments and testimonies of esteem showered upon them.

The Directors of the British South Africa Company gave a luncheon on Thursday to the three colleagues who had inspected for them the valleys of the Mazoe district, north of Salisbury. This Surgeon-General Gorgas reported to be naturally well drained and salubrious, so that it cannot be considered as essentially malarial. The precautions against anopheles mosquitos should therefore be increased for these insects could most certainly be more easily controlled in Rhodesia than in such a region as Panama. The local administration is carrying on an efficient campaign deserving of commendation to exterminate malaria in the company's districts where it still prevails.

The dinner (on Monday) was quite an Anglo-American commemoration of medicine and science. After the usual loyal toasts Lord Bryce gave the President of the United States and referred par-

ticularly to the Carnegie and the Rockefeller Institutes and the International Health Commission, then holding up the President as a conspicuous example of a man having wide learning and brilliant literary gifts as well as solid judgment and capacity for great affairs. The American ambassador in responding said Surgeon-General Gorgas won his way to his position and was well entitled to whatever honor they could bestow. His elevation was a good measure of the President's discernment and wisdom. It needed a trained mind thoroughly to appreciate the value of a trained mind. In this and also in politics, President Wilson had shown that a trained mind was the chief instrument of success. Sir Havelock Wilson proposed the health of Gorgas himself and said he had fully justified the wisdom of the men who selected him for the task and gave him a free hand. Havana, a hotbed of yellow fever for generations, had been cleared by his work in nine months, and the scourge of Panama had been eliminated. But one could boast of a share in his exploit as it was based on the work of Sir Patrick Manson and Sir Ronald Ross.

In reply Surgeon-General Gorgas spoke of their obligations to their brave predecessors who had made the discoveries which rendered their work possible. But for those discoveries they would probably have done no better than the tireless workers of twenty-four years ago under French leadership.

On Monday afternoon at the Royal Society of Medicine we had a good opportunity of observing in another capacity the man we had been lionizing, for Gorgas himself read a paper on the Panama Canal in which he described the precautions they had to take and the methods they employed to insure the destruction of yellow fever and of malaria. They determined to make an effort to get rid of the disease carriers and prevent their reproduction. Therefore they laid it down that the larvæ were to be considered offensive nuisances and issued an ordinance to the effect that any person having mosquito larvæ on his premises would be liable to fine or imprisonment. In effect punishment was very rarely inflicted. It was surprising, he said, to how great a degree men of the Latin race were influenced by kindness and gentleness—especially surprising to Anglo-Saxons who were accustomed to the rougher methods of police courts. The most important measure carried out was drainage and this was under the surveyance of inspectors. He looked upon the use of oil as more or less a confession of failure; yet a thousand barrels a month were used at the canal work. A carbolic solution was largely employed as a larvicide. Enormous quantities of quinine were consumed for about half the force were induced to take a dose once a day as a prophylactic. He mentioned, too, that in the early stages a good deal of work outside their department was thrown upon the engineers; as an example they took charge of the church organization.

Mayor Noble, at the conclusion of the lecture, exhibited a number of illustrative slides. Surgeon-General Gorgas also, in reply to a question, said several cases were brought on from the outside, but had never given rise to others.

A sad story comes from West Bromwich—suicide of one of its leading practitioners, Dr. Plummer, under an erroneous idea that he was to blame for the death of a patient. He left a note to the coroner to say in such a case a man ought not to live and belong to the profession to which he always hoped to be a credit. The death was one after childbirth. Experts testified at the inquest that the doctor's self-reproach was uncalled for as the case was a very uncommon one, that he had done everything possible and the woman's death was in no way due to anything he had done or left undone. The jury returned a verdict of suicide while of unsound mind.

Dr. Leonard Williams was asked to open a discussion at the Chelsea Clinical Society on "Arteriosclerosis," which he did in a capital speech repudiating many notions that are common enough. He prefaced his objections to them by one as to the term selected as the title of the discussion. "Arteriosclerosis," he said, "is not only a bastard, but a parvenu, like all bastards and parvenus, it is deceitful, observing the true and suggesting the false." Se he proceeded to speak of arterial degeneration as more "in conservance with dignity, both etymological and scientific." I sympathize with him. Our literature abounds in words even more offensive—some of them as misleading as politicians' statements.

The project of a Family Medical Encyclopedia attracted attention from the way in which it was advertised with the names of about a score and a half of distinguished medical men as leading contributors. So much indignation was expressed that most of these contributors repudiated their share in the matter and wrote to the newspapers that they only corrected the proofs or advised the editor on some points. The first number—for it is coming out in parts—has now appeared and is full of advice which calls for condemnation as at the least promoting dangerous self drugging. But that is another question. The names of the contributors and their qualifications are set forth for the admiration of the "family" readers. No doubt we shall again be favored with columns of indignation at this and fresh repudiations and explanations almost rivaling the "honest misunderstandings" of prevaricating politicians.

I don't know that the wife of a doctor differs so much from other married ladies as to need a special society to tell her the essentials of success in domestic economy, dress, furnishing, the purchasing power of money, and so on. But such an organization is proposed and steps are being taken to establish it. An insert of *The Hospital* of March 21 invites candidates to join in the attempt to form a cooperative society for such persons. Every candidate must on applying declare she is a doctor's wife—no others being eligible. If 1,000 join before May 2 the promoters will go forward and the doctors' wives, duly dubbed D. W., will be able to obtain advice on the management of their households and every other assistance. Let us hope the management of their husbands will not be included. It is common enough to hear that married ladies are apt to resent interference or even advice from their mothers-in-law. How they will embrace the opportunity of enjoying the attentions of a cooperative union of mothers-in-law remains to be seen.

---

**Hematoma Auris; Operative Treatment.**—G. J. Jenkins reports the case of a woman, aged 32, in whom a hematoma was the result of a blow. When seen next day the swelling involved the whole of the internal surface of the cartilaginous part of the pinna, and was about the size of a hen's egg. An incision was made along the margin of the helix. The blood was on the external surface only and extended somewhat into the meatus.—*Proceedings of the Royal Society of Medicine.*

**6. Infantile Scorbutus.**—J. L. Morse states that there has been a rapid and progressive increase in the number of cases of scurvy coming to the Medical Out-Patient Department of the Children's Hospital during the last four years. This increase has been not only absolute, but also relative to the total number of cases. A summary of the author's figures shows that 18 or 20 per cent. were fed on "stale" foods, that is, condensed milk or prepared foods mixed with water. Forty-four or 50 per cent. were fed on either prepared foods or condensed milk. In the thirty-seven cases in which milk was used either with or without prepared foods and data were given as to whether it was heated or not, the mixture was given raw in one, or 3 per cent.; pasteurized in six, or 16 per cent.; boiled, scalded, or sterilized in 30, or 81 per cent. It is probable that the milk was boiled in at least one-half of the other cases in which milk was used with prepared foods, because the directions on the can containing the food used in these cases call for boiling. It is also probable that in a considerable proportion of the cases on modified milk prepared at milk laboratories the mixture was pasteurized. It would appear from these figures that prepared foods, "stale" foods, and the heating of milk to the temperature of pasteurization or higher may all play a part in the etiology of scurvy. The fact that three cases developed in babies taking only breast milk shows, however, not only that no one of these can be the exclusive cause, but also that there must be some other cause. The most striking fact in these figures is, however, that 54 of the 58 cases, or 93 per cent., in which there are data as to the freshness of the food, were fed on foods which were not fresh, that is, containing either no milk or cooked milk.

**14. Hemorrhage Following Tonsillectomy.**—F. E. Garland and D. C. Greene state that the question as to why, following a tonsillectomy, one patient bleeds and another does not is a perplexing one. The bleeding is not necessarily due to excessive trauma or careless cutting of the constrictor muscle. In practically all of the cases the authors have seen, which number about one hundred, the bleeding has occurred following easy operations in which the tonsillar fossæ and pillars of the palate remained entirely intact. A possible explanation, which they have been unable to verify, is this: there is often noticed in the fossa after removing a tonsil a plexus of small veins due possibly to chronic inflammation. It is possible to conceive of the knife or snare splitting open one of these veins longitudinally so that in the movements of the throat the forming clot is continuously expelled from the remaining part of the vein, and bleeding is produced. Be this as it may, it seems to the authors that the bleeding is more often venous than arterial. Small arteries which are seen pumping in a throat just after removing the tonsil usually cease bleeding in a few minutes and do not require ligating. The dangerous type of bleeding, the kind which goes on to exsanguination and death, may be described as an ooze. This continues for hours without giving any of the textbook symptoms of hemorrhage. The blood may be expelled by coughing, but the half-conscious patient more often swallows it. Accordingly, unless vomiting occurs, hemorrhage may continue without the slightest evidence. The authors have recently seen such a case in which the nurse, of more than average experience, did not detect bleeding until ten hours after operation. She noticed that the patient, a child, swallowed frequently, but not until a large quantity of blood was expelled from the stomach did she realize the danger. Safety from this danger lies in a careful inspection of the patient's throat at intervals after operation. Although such inspection may not disclose the actual bleeding point, owing to the obvious difficulties in the way of obtaining a good view of a semi-conscious patient's throat, and to the fact that the bleeding may be low in the fossa and thus escape detection, there is one sign which is unfailing in these cases, and that is a clot which forms in the fossa above the bleeding point. This clot is always present, and its presence is sufficient evidence of bleeding. When removed it quickly reforms. This danger signal appears at the beginning of the bleeding, and not as most signs do, when death is near. By careful observation of the throat, and an early detection of the clot, one is enabled to deal immediately with the situation. One should not wait for other signs, but should at once suture the pillars. This process takes about three minutes, and as but little blood is lost the patient's recovery proceeds in the usual manner.

**17. Diagnosis of Enlarged Thymus and Symptomatology of Hyperthymatism.**—P. H. Sylvester points out that one should be on the lookout for enlarged thymus in cases of asthma, persistent bronchitis, and laryngeal or tracheal stenosis. Inasmuch as the percussion outlines correspond so closely with those shown by the roentgenograms, the enlarged thymus should be found on examination by the ordinary methods of physical diagnosis, of which threshold percussion is apparently accurate and satisfactory in the hands of one familiar with children. Children showing an enlarged thymus present two fairly uniform sets of respiratory symptoms: those due to pressure on the trachea, as shown by cyanosis, slow, labored breathing and supraclavicular and substernal retraction, and those presumably due to toxemia or hypersecretion of the thymus, namely, breathing of the asthmatic type characterized by fairly easy inspiration and long, difficult expiration, accompanied by râles. Inasmuch as in all the cases treated by the author the symptoms for which treatment was instituted disappeared when the physical evidences of enlarged thymus disappeared, there is a casual relationship between the enlarged thymus and

the pressure symptoms, and the enlarged thymus and the asthmatic symptoms, which were obviously not due to pressure and were therefore probably due to hypersecretion. Pressure symptoms and toxic symptoms may be combined in the same case, but those of the toxic type are more constant.

**19. Lymph Cyst of the Mesentery.**—C. G. Mixter notes that there are four methods of procedure in the treatment of mesenteric cysts: (1) Aspiration, which has been practically discarded on account of the large percentage of recurrences; (2) enucleation, which can be applied only in a limited number of cases owing to the interference with the circulation of the intestine on removal of the cyst; (3) marsupialization, or drainage of the cyst by stitching its walls to the anterior abdominal parietes; (4) extirpation of the cyst with resection of the adherent intestine. The last is the method of choice and though Coley stated three years ago that the mortality is forty per cent., this is undoubtedly lower at the present time. Drainage of the cyst by connecting it with the abdominal wall is useful in cases where a radical removal is impossible or where there is severe infection. Treatment of the cyst by this method does not lead to the establishment of permanent fistulæ.

**2. Advantages and Disadvantages of Quarantining Hospital Wards for Measles.—E. E. Graham** presents some of the ideas that have occurred to him as regards the treatment of children in a ward where a case of measles has broken out. The object should be to reduce the number of patients in a large ward as rapidly as possible and transfer them to a small ward. If the parents desire to take a child home, one ought to allow them to do so, provided the child is over three or four years of age and can secure good medical attention and nursing at home. The board of health should be given the names of such children. If a child has previously had measles and is convalescent one ought to send this child home without consulting the parents. It will not carry the disease and is sufficiently advanced in convalescence to leave the hospital. It is of no advantage to keep this child in a hospital for three to six weeks. If it is an only child it should be sent home whether it has had measles or not, provided it is over three years of age and can, if measles develops, receive good medical attention and nursing at home. If it has not had measles and the other children of the household have had measles the child should be sent home if over three years of age and the conditions at home are favorable for good nursing and care. All other children should be kept in strict quarantine in the hospital for fourteen days after the rash appeared in the measles case. These children may, however, be transferred to a room or small ward and the large ward scrubbed, fumigated, and immediately put into use. If a child over three or four years of age has previously had measles it may be admitted to the ward if acutely ill, the parents being informed that it will be exposed to measles. All the beds in the ward should be separated by glass partitions; if a case of measles occurs one should remove the measles patient and also the child on either side of the measles patient, and the ward should be scrubbed over a space of twenty feet around the measles patient and patients should then be admitted to the ward.

**3. Dreams.**—A. L. Benedict states that dreams seem to depend largely upon afferent stimuli, as of cold or heat, pressure or pain, or upon the recollection of experiences received during the day, or at least recently, or else upon the continued mental action along the same lines which have been pursued in the day's work. Strong desires, emotions, and experiences may or may not be manifest in dreams. So far as subjective experience with dreams is concerned it has seemed that the kind of dream that ought naturally to be expected has been lacking, and that the stimuli which produced the dream were of a trivial nature, which did not make any particular impression during their actual experience. In a general way, however, dreams represent personal matters of interest. A further point to which collective study should be directed is the frequency with which mental problems unsolvable during the waking period have been carried to completion in dreams.

**4. The Mischief of Free Medical Service.**—W. S. Gottheil believes that the prime source of failure in the public ambulant medical service in New York City is the fact that the community is attempting to get something for nothing. But the dispensary physician will be paid in one way or another, like every one else, or his work will be worth just what it costs, which is nothing. There are two ways in which the dispensary physician can take his pay: (1) In experience. The public clinic is the post-graduate field of development for the embryo specialist, and in some cases this may be regarded as a partial return for services rendered. But this entails, on one hand, large classes of patients, for most cases are entirely routine, of no interest or value, and attention to them is merely unrewarded drudgery. (2) In getting private patients. The dispensary authorities necessarily frown upon this form of remuneration, since it is directly opposed to their interests. But the author holds that this practice is absolutely legitimate, and he knows that it is done in every ambulant medical institution of which he has any knowledge. The burden of medical charity must be placed where it belongs—on the community; and a community like New York City that collects and spends the revenue of a kingdom every year will not be loath to assume this burden when once the necessity is realized. Medical services to the sick poor, if these services are to be efficient and conscientious, must be paid for like any other services. Volunteer service is unsatisfactory and seems likely to remain so. It takes advantage of the unorganized state of the medical profession to exploit its members and is unworthy and undesirable.

**3. Examination of Illiterates for Mental Defectiveness.**—M. H. Foster concludes that there is no one test for feeble-mindedness, and that only by a routine examination of all the mental faculties can one make an accurate diagnosis. The amount of acquired knowledge and the capacity of the mental functions should both be measured. Physical signs and facial appearances are of but little use in picking out defectives. The examination should be conducted along scientific lines with a clear comprehension of the psychological basis of all the tests employed.

**5. Spinal Surgery.**—R. Wallace discusses the surgical treatment of spinal cord injuries with special reference to the decompression treatment by laminectomy. The operative possibilities are limited, but a discriminating diagnosis of the site and nature of the lesion should be made promptly, and operative interference should be resorted to whenever feasible, before a greater or permanent damage to the cord results. A simple laminectomy affording decompression to the compressed cord has within the last few years given striking results. It has been shown that several laminæ and spinal processes can be removed with but little detriment to the patient and but slight danger of trauma to the cord. An incision is made over the spinous processes; the laminæ are freed by blunt dissection from the overlying musculature and thoroughly exposed. By means of a chisel, saw or forceps, the laminæ are freed close to the transverse processes and removed. An aperture somewhat more than the diameter of the cord must be insured to give free and unrestricted decompression. Care should be taken not to wound or open the dura unless there is special indication. A wide exposure of the canal is necessary and the angulation of the cord is completely relieved. Occasionally it becomes necessary to open the dura and examine the cord, but the opening should be closed carefully with catgut. The muscles and aponeurosis should be approximated and the skin closed with linen, reinforced, if desired, with silkworm gut. Drainage should not be employed. The scar tissue which forms is exceedingly fibrous and at times shows a reformation of bone. The cord is well protected and the spine needs no special support except in cervical fractures. Within a few days the patient may be changed from side to side and bolstered with pillows. The bowels and the bladder should receive attention and soon faradism and massage may be used. In spite of the advice of Elsberg as to the need of conservatism in recent fractures of the spine and injury to the cord, the author states that with bone pressure threatening the destruction of the cord some of the most startling results have been obtained by prompt interference. Early operations undoubtedly give the most satisfactory results, and the author reports four cases in his own practice. In all laminectomy was performed except in one, a gunshot wound shattering the transverse process of the twelfth dorsal vertebra. There were very slight symptoms of compression but more of irritation in this case, and the patient rapidly recovered. The question of operation must be decided with each individual case, but spinal decompression by adequate laminectomy should not be postponed without good and sufficient contraindications.

**7. Paratyphoid Fever.**—L. D. Bristol notes that in laboratories in which bacteriological examinations are made, a suspected serum should be tested for paratyphoid aggultinins, both A and B, after the serum has been pronounced negative three times so far as the true typhoid Widal reaction is concerned. More accurate studies and blood cultures should be made in all cases which resemble typhoid fever. An anti-paratyphoid vaccine should be tried in the treatment of the disease, and as a measure of prevention such vaccines should be used either alone or in combination with a typhoid vaccine.

**11. Ninhydrin Reaction in Urine.**—C. Jamison finds that whenever the urine is strongly acid in pregnant women, the ninhydrin test gives a negative result. In ten non-pregnant women suffering from various surgical conditions the urine gave a distinct positive reaction, as was also the case of four other non-pregnant women and two men, one of the latter suffering from nephritis. The urines of four healthy men were tested on another day and all gave negative reactions. In view of these results it was thought that the amino-acids present might be accounted for by the action of the bacteria on pus and other albuminous matter present in the urine, especially in that of women. To avoid this the urine was thoroughly boiled as soon as voided, and all the material used in the tests was handled under aseptic precautions. Under these conditions ten urines from non-pregnant women suffering from various surgical conditions and two from pregnant women were tested. At the end of twenty-four hours the dialysates from eleven of them showed positive reactions with a freshly prepared solution of ninhydrin, and one of them a negative reaction. The case giving a negative reaction was one of carcinoma of the breast. The author's conclusions from the experiments were as follows: (1) After dialyzing the urines of pregnant women the dialysate always gives a positive reaction to ninhydrin. (2) After dialyzing the urines of non-pregnant women the dialysate frequently gives a positive reaction to ninhydrin, occasionally under the same conditions the urines of men give positive reactions.

5. A Case of Malarial Coma Lasting 46 Hours; Recovery. A. G. Tresidder.

**4. The Effects of Drinking-Water in the Causation of Dental Caries.**—J. B. Cook points out an association between excessive softness of water and an increased amount of dental caries among the school children. The environmental conditions, so far as it is possible to measure them, do not seem to be a source of the relation between the hardness of water and the amount of dental caries. These correlations and partial correlations merely call attention to an association between the nature of the drinking water and the amount of dental caries and must not be regarded as necessarily indicating cause and effect. There may well be other factors at work which have a greater influence.

**5. Malarial Coma Lasting Forty-six Hours: Recovery.**—A. G. Tresidder reports a case of this condition in a gunner, aged twenty-three, serving in the Punjab. Although the diagnosis of this case was not confirmed by the blood examination it seemed to the author that there could be no doubt that this was a case of malignant malaria. The fact that the patient had been well dosed with

quinine before the author saw him would have accounted for the absence of parasites from the peripheral blood. The possibility of the case being one of uremia was fully negatived by the following facts: (1) The daily quantity of urine passed was normal. (2) The albumin only amounted to a trace, which disappeared with the subsidence of the fever. (3) No examination revealed the presence of casts. (4) No history of any etiological factors of nephritis could be obtained. (5) The administration of quinine in full doses resulted in a complete cure. The essential pathology of this condition has been conclusively proved to be due to the blocking of the small cerebral vessels with parasite laden corpuscles. One's object in treatment must therefore be to destroy the parasites and to flush them out of the blocked capillaries. In the author's opinion these cases should therefore have been treated energetically and persistently with quinine, commencing with an intravenous injection of 5 to 10 grains of the bihydrochloride in a pint of saline solution, and subsequently giving intramuscular injections of the same drug in 10-grain doses twice a day until consciousness was restored. The administration of salines intravenously and per rectum have accomplished the second object. One must not, however, be satisfied with the disappearance of the acute symptoms and the apparent restoration to normal health, for the liability of malignant malaria to recur even after a return to temperate climates and after long intervals is a well-known clinical fact. Some even doubt whether malignant malaria can ever be cured, but the author thinks that one is hardly justified in taking such an extreme view. Five grains of quinine in tablet form should be taken every other day for a period of at least three months, and the author thinks that if this method of treatment is conscientiously carried out few cases will recur. In the event of the slightest recurrence resort should be taken at once to the intramuscular method of treatment, which is of especial value in combating this form of malaria. The author has never seen any harm result from injections of quinine; there is no risk of tetanus if the injection is made under strict aseptic precautions.

7. The Milroy Lectures on the Hygienic Aspect of the Coal-mining Industry in the United Kingdom. F. Shufflebotham.

**1. The Auditory Method in Blood Pressure Estimation.**—J. A. McWilliam and G. S. Melvin point out that it is being gradually recognized that systolic pressure estimation, though valuable, gives very insufficient information regarding circulatory conditions in health and disease, and that a knowledge of the range of pressure change during the whole cardiac cycle would be of great importance in various ways. The auditory method, employed in a certain way, offers distinct advantages in the estimation of the systolic pressure, but its greatest importance lies in its relation to the estimation of diastolic pressure. The simplicity, ease, and rapidity of the auditory method are strong points in its favor. It gives all the information that is to be obtained by more cumbrous and time consuming methods, and with greater precision, the index being a much sharper one than is present in other methods; it also causes less disturbance to the patient than slower methods which involve a longer compression with the armlet. In the cases in which the Erlanger or the Pachon apparatus gives dubious or unreadable indications the auditory method has always in the authors' experience given a definite verdict. It is greatly superior to the palpatory and sphygmographic methods that have been proposed. The authors are satisfied that all the evidence as to diastolic pressure gained by the other methods and much more also can be better obtained by the simple and quick auditory method. The diastolic estimation in this way is as easy as that of systolic pressure, and is relatively little if at all complicated by certain sources of fallacy (for example, state of arterial wall) which may come into question in systolic estimation. This method, measuring the diastolic as well as the systolic pressure, has the great advantage, as compared with the ordinary tactile method, of giving the numerical range of pressure variation in the artery during the whole cycle of the pulse beat; that is, the pulse pressure range.

**3. Pancreatic Cysts.**—H. Bethan Robinson reports three cases of pancreatic cyst, which were operated on successfully and which were of different types, the first an isolated cyst in connection with the back of the head and the other two of the prepancreatic or peripancreatic variety. The first, apart from other features, was of interest from the viewpoint of the diagnosis. The possibility of the existence of an enlarged gall gladder was considered, but the freedom of the cyst from the liver and its apparently deep and retroperitoneal situation made this improbable. The two other cases had much in common clinically. In Case 3 the cyst pushed its way forward between the stomach and the transverse colon, perhaps in the more usual direction. In Case 2 the cyst projected above the stomach, pushing it downward and toward the left. They were both what Korte, Osler, and others have described as "pseudocysts," but not of that form to which the same term is also applied in which the effusion occurs primarily into the lesser sac of the peritoneum. The onset of both was attended by acute symptoms, starting without any apparent cause, and both were associated with destructive changes in the gland tissue.

**4. A Renal Cyst Causing Chronic Intestinal Obstruction.**—E. C. Bevers reports a case of this condition in a woman fifty-two years of age. He notes that the interest of this case was in the difficulty of diagnosis. The swelling appeared to be cystic and to have a point of attachment in the left lumbar region. The diagnosis made before the operation was that of a mesenteric cyst, and even when the abdomen was opened this was the impression given; it was only when the left kidney came into view that the true nature of the case became clear. A renal condition had not been considered, as there was no swelling or resistance in the left loin, and the latter area was resonant; also the extreme mobility of the tumor and its obvious intraperitoneal nature seemed opposed to a condition connected with the kidney. Renal tumors either have the colon in front of them or push it toward the middle line; it is rare to find them becoming pedunculated, and to all intents and purposes they are intraperitoneal structures to the inner side of the colon, as in this case. Large single renal cysts may be of a serous nature, springing from the cortex of the kidney while the rest of the kidney is healthy, or they may be paranephric cysts originating in renal or adrenal rests. Both serous and paranephric cysts may be connected with the pelvis or one of the calices of the kidney by a narrow channel. The symptoms that these large cysts give rise to are due to pressure on surrounding organs. The second point of interest in this case is the chronic intestinal obstruction produced. This was brought about in two ways: in the first place the splenic flexure of the

colon was constricted where it passed around the neck of the cyst, and in the second place the heavy cyst itself was pressing upon the descending colon.

### Berliner klinische Wochenschrift.

*March* 16, 1914.

**The Ehrlich-von Behring Number.**—Since two of Germany's most distinguished scientists chanced to be born almost simultaneously sixty years ago, this number of the *Wochenschrift* is virtually a jubilee affair, being made up almost entirely of papers which comprise memories and appreciations of the two men, along with contributions from pupils of the latter and co-workers in the same field. The tribute is practically international in scope. A simple enumeration of the contributions with an occasional word as to their purport, must necessarily supplant for the nonce any attempt to single out the leading articles of the journal. The opening article by Lazarus is a brief appreciation of Ehrlich, with special reference to the enormous obstacles surmounted by the latter, and especially his fight for the introduction of salvarsan therapy, and his defence of the latter against hostile criticism. This struggle he has shared in common with von Behring—as shown by Much's appreciation. Both men succeeded in introducing into world-wide usage remedies little short of heroic, which, while bringing about enormous reductions in morbidity and mortality, have been repeatedly accused of numerous untoward effects, insignificant indeed when compared to the beneficent consequences. One knows not which is the more admirable in the parallel cases—the struggle to champion the cause once entered upon, through a wealth of data and dialectic, or the more self-effacing efforts to improve the products and the technique of their use. This should be and generally is the fate of all pioneers in science, and our two have accepted their lot with more than common steadfastness. Richet of Paris contributes a few words concerning Ehrlich as the logical successor of Pasteur and Koch. Heubner, the eminent Berlin pediatrist, gives a retrospect of what von Behring has done in antagonizing diphtheria, a children's plague. Salomonsen in an open letter to Ehrlich recalls the students at the summer term, Breslau, 1877, who have since made their mark. In this connection he quotes Welch of the United States, who refers to those "wonderful days." There were assembled together Ehrlich, Weigert, Welch, Lassar, Rosenbach and many others who afterwards attained distinction. The teaching body was naturally composed of men of the highest efficiency. Lesser and von Zeissl contribute articles on the modern treatment of syphilis, chiefly, of course, dealing wth salvarsan therapy. Calmette of Lisle and Bordet of Brussels, both Pasteur Institute directors, discuss the lipoid content of the blood, merely "in honor of the two great savants" to whom the number is dedicated. Babès also contributes, from the same viewpoint, a technical study of the metachromatic corpuscles of acid resisting bacilli. Römer writes exhaustively on the diphtheria bacillus, while Flexner, in a complimentary paper, gives the most recent finds and theories of acute poliomyelitis. Carrel reports continuous finds in a cultivated strain of connective tissue, while Noguchi discusses the latest methods of bacteriological study of infectious diseases. Pawlow writes on the instability of the reflexes of internal inhibition. Two Moscow men report a case of rhinoscleroma of bacterial origin (Frisch's bacillus), unsuccessfully treated by an auto vaccine, although improving under *x*-rays, radium, and carbonic acid snow. After passing several papers on indifferent subjects we find a long article by Maragliano on antituberculous vaccination, while Wassermann discusses the nature of the reaction which goes by his name. Finally Roux and Metchnikoff jointly contribute a paper on Ehrlich's life work.

### Münchener medizinische Wochenschrift.

*March* 10, 1914.

**Ehrlich Jubilee Number.**—This number of the *Wochenschrift* deals with Ehrlich's sixtieth birthday and with his work, notably in the direction of the salvarsan treatment of syphilis. Gennerich gives the results of treatment in the Marine Hospital at Kiel. Schreiber attempts to demonstrate the rationale of action of both salvarsan and mercury in syphilis. Dreyfus narates three years' experience with salvarsan in diseases of the nervous system and Iwaschenzoff contributes a similar paper. Leredde gives the technique of the salvarsan sterilization of syphilis. Wechselmann and Eicke limit themselves to the use of neosalvarsan, and Katzenstein confines himself to the intravenous exhibition of the latter. Seyffarth writes of concentrated neosalvarsan. Hasdrat and Lesser each describe syphilitic reinfection following salvarsan treatment; Pöhlmann discusses drug anaphylaxis. Plaut gives a brief appreciation of Ehrlich. Among these numerous contributions we can do no more than cite almost at random some salient points. Gennerich believes that salvarsan is specially indicated in syphilis in the public arms of defence. The subjects are young and vigorous and the proper use of the drug, say within the first six months, ought to result in a permanent cure. Iwaschenzoff deduces from material in St. Petersburg that salvarsan can undoubtedly benefit tabes dorsalis, as a form of syphilis of the nervous system, everything depending on proper technique and dosage. It cannot be seen that the other writers on the salvarsan therapy come to any new and definite conclusions. Hardrat sums up his two cases of reinfection as follows: Both were examples of late primary or secondary syphilis when first seen and were treated rationally year in and out with Wa R negative and fully normal liquor. Both subjects reappeared at the same time with new chancers (not chancre redux). Secondary phenomena appeared tardily and both gave a positive Wa R in the cerebrospinal fluid. One patient, heretofore healthy, developed syphilitic cachexia. In neither case was there a positive spirochete fluid. Lesser's case warns us that in all cases in which a married man is infected out of wedlock the wife should be examined. The man in the case had become reinfected after a neosalvarsan cure and had infected his wife during his second attack. In his article on drug anaphylaxis Pöhlmann states that considering the enormous recorded material we are still deeply ignorant of the rationale of the subject. It is not identical with drug idiosyncrasy, yet the two must be closely related to each other. Old experiments and clinical phenomena are cited to show the transmissibility of an acquired anaphylaxis. Qnite recently the author studied these subjects in connection with a quinine rash. The patient, a young married woman, took quinine for a cold in the head. Two powders were taken two hours apart. Soon after the second dose had been taken the patient's face became hot, her hands reddened, and itching mascules appeared. She remembered that she had once had a similar experience after taking a powder of unknown nature. The exanthem pursued a rather severe course, and consisted of papules and wheals. Animal experiments carried out under the usual conditions showed that the quininized serum of the woman caused the symptoms nroduced by quinine alone. No true anaphylaxis was present, therefore, and we can only state that the woman had simply been poisoned by the quinine, to which she showed great vulnerability.

## Insurance Medicine.

**General Life Insurance Medicine.**—Florschütz divides his subject into twelve captions, of which four refer to fundamental principles and eight to the external and internal factors in medical selection. The original matter appeared in the "Insurance Library," a recently published work of reference. The editor of the *Blätter* reproduces in this number but one chapter of the original which deals with our notions of normal, adaptable, and substandard risks. Selection is entirely up to the medical directors of the company—in Germany the revising physician. A normal risk has a certain average expectation of life. It is at once apparent that for substandard risks we have no such guide to serve us. Insurance examiners, however, know that a certain percentage of normal risks are doomed to unforeseen premature deaths. However it happens, these very subjects are most strongly attracted to life insurance. For one reason or another, they fear an early death. Many such actually present evidence through which they are made uninsurable, although many a man technically insurable is already doomed, and is really a substandard risk of an extreme type. Closely related with this subject is that of the fallibility of medical selection for the early years of insurance. Medical selection, however, cannot be made more rigorous; in fact, according to some it has already gone too far, for it throws out insurable material, just as it accepts uninsurable material. The first named, as technically substandard risks could be insured for some term; while the latter, despite all calculations, may die at any time. Owing to the sharp competition of companies, substandard risks are welcomed. This term is of course very vague and might be made the subject of classification to some extent, based on average mortality statistics, which should exceed to a certain degree the same figures for normal risks.

The normal risk may be defined as one readily passed by examiner and medical director. The next class, that of "adaptable" risk, is determined largely by the revision department. This corresponds apparently to a class of risks in the United States which are held up *pro tem*, until certain conditions have been complied with—the disappearance of this or that symptom after a period of observation. The line between these and substandard risks is of course difficult to draw, at least in certain cases. In Germany the examiner of revision, naturally a man of unusual experience, actually examines the risk for the company, while with us he as a rule sees only the report of the examiner.—*Blätter für Vertrauensärzte der Lebensversicherung*, 1913, November-December.

**Ever-Increasing Interdependence Between Life Insurance Companies.**—In speaking on the above subject Mr. Henry Abels, President of the American Life Convention, shows that through all the vicissitudes that the life insurance business has experienced, it has emerged stronger and better, and more favorably understood by the insuring public than ever before. All of the improvements made have been brought about through a realization by all those having to do with life underwriting of their interdependence, crystallized into active cooperation. As the several parts of a building work independently, yet supplement each other, so the structure of life insurance is dependent in the same manner upon the companies composing it. Whatever benefits one company is an advantage also to the others; whatever injures one works a detriment to all.

Human life—the most vital asset of the nation—is the essential element of the institution of life insurance. Interdependently must the companies, as benefactors of mankind, seek to educate the masses with regard to prevention of disease and conservation of health—thus lessening sickness, suffering, and sorrow, and promoting the happiness of the race. Conservation has become the keynote in the economic and industrial world to-day. Life insurance—than which there is no greater influence for economic and social advancement—has embodied in its very existence the supreme idea of conservation. The life companies, responding to present-day needs, are directing their forces toward increased action in placing the institution of life insurance as a foremost factor in the general conservation movement. Again is seen the interdependence of the companies. Through the combined efforts of many of the companies results have been produced in conserving the interests of humanity through life insurance.—Association of Life Insurance Presidents, December, 1913.

**A Test for Albumin in Urine.**—A. E. Osmond presents the following test for albumin in the urine. It has been given a thorough trial with all sorts of urines for over a year, and has been checked up by controls made by the nitric acid, the ferrocyanide acetic acid, and the heat tests, and has proved to be equal in delicacy to any of those mentioned and to possess furthermore certain features which make it superior to them as a routine measure.

Picric acid, 5.00; citric acid, 10.00; sodium chloride, 100.00; distilled water, 1000.00. This gives a solution yellow in color—practically the amber of clear urine; a specific gravity of 1065 at 15° C.—which is much heavier than that of urine, and containing no chemicals which react with anything but albumin.

Technique.—Place two or three c.c. of the reagent in a test tube. Filter the urine until it is perfectly clear. Then allow the urine to float very gently upon the surface of the reagent. Albumin will be shown as a white zone at the line of contact of two amber fluids.

Advantages.—(*a*) The reagent being isochromic with the urine the white ring of precipitated albumin is shown very clearly. (*b*) The reagent contains no chemicals which react with any urinary pigments, bile, etc., therefore no color zones are formed which might hide a small amount of albumin. (*c*) The heavy specific gravity—1065—prevents ready mixing of the urine and the reagent; thus, should albumin be present, it is not apt to be diffused and overlooked. (*d*) The reagent keeps indefinitely—it is always ready for use. (*e*) If spilled this reagent does no damage to clothing or fabrics. (*f*) Boiling produces no change, nor is it dangerous. In cold weather with a urine cloudy from phosphates which the filter does not remove, boiling the reagent first is a distinct advantage as the hot reagent restores the clearness to the urine as the fluids come in contact. (*g*) The reagent does not throw down crystals of salts of urea or nitrogenous substances in concentrated urines. (*h*) In cold weather there may be a feathery deposit of crystals. These settle to the bottom of the bottle and may be removed by filtration or brought back in solution by heat. The activity of the reagent is not affected.—*Lancet-Clinic*, December 13, 1913.

# Book Reviews.

TUBERCULOSIS—ITS CAUSE, CURE, AND PREVENTION. A Revised Edition of "The Great White Plague." A Book for Laymen. By EDWARD O. OTIS, M.D. Professor of Pulmonary Diseases and Climatology, Tufts College Medical School; late President of the Boston Tuberculosis Association; late Visiting and Consulting Physician to the Massachusetts State Sanatorium. Price, $1.25 net. New York: Thomas T. Crowell Company, 1914.

DR. Otis has written a popular work on tuberculosis, and has accomplished this object excellently well. Such a work is always welcome, for in a campaign against tuberculosis, if it is to be effective, it is absolutely necessary that the public shall be educated concerning the salient facts of the disease and especially with regard to preventive measures. Insistence is laid upon the necessity for treatment of tuberculosis in the incipient stage, and a much needed warning is uttered against allowing the disease to gain too firm a hold before consulting a physician. All phases of the malady are fully discussed and in such clear language, that the lay reader will have no difficulty in following and comprehending the text. The book should act as a beacon light to those afflicted with tuberculosis and should rank high as an educative factor among the community at large.

THE ELEMENTS OF BANDAGING AND THE TREATMENT OF FRACTURES AND DISLOCATIONS. By WILLIAM RANKIN, M.A., M.B., Ch.B. Dispensary Surgeon, Western Infirmary, Glasgow; Extra Honorary Assistant Surgeon, R. H. S. C., Glasgow. With sixty-eight original illustrations. Price, $1.50. London: Henry Frowde; and Hodder & Stoughton, 1913.

THIS is an elementary work intended as a guide for the medical student in his work in bandaging and the treatment of fractures and dislocations. Emphasis is rightly placed on the commonest conditions and complications, and the methods employed are simple and serviceable.

CLINICAL DIAGNOSIS AND URANALYSIS. A Manual for Students and Practitioners. By JAMES RAE ARNEILL, A.B., M.D.; Professor of Medicine and Clinical Medicine in the University of Colorado; Physician to the Denver County Hospital, St. Joseph's Hospital, and St. Luke's Hospital, Denver; Consultant to the Children's Hospital, Denver; Member of the Advisory Board of St. Joseph's Hospital for Consumptives and New Mexico Cottage Sanitarium, Silver City, New Mexico. Second Edition, Revised and Enlarged. Illustrated, with 83 Engravings and a Colored Plate. Price $1.00 net. Philadelphia and New York: Lea & Febiger, 1914.

THIS little book should prove useful to students and practitioners. It contains all that they are likely to require on the subjects of clinical diagnosis and uranalysis, and the methods of procedure have been selected with unusual skill. Lengthy and time-consuming processes are omitted, and possible sources of error are indicated. The reader will find in this volume the usual tests for blood, stomach contents, feces, sputum, and urine; and several of the newer procedures, such as cryoscopy, examination of the cerebrospinal fluid, and various serum reactions are included.

MATERIA MEDICA, PHARMACOLOGY, THERAPEUTICS, PRESCRIPTION WRITING. For Students and Practitioners. By WALTER A. BASTEDO, Ph.G., M.D., Associate in Pharmacology and Therapeutics at Columbia University; Assistant Attending Physician to St. Luke's Hospital, New York City; Consulting Gastroenterologist to the Smith's Infirmary and to the Red Cross Hospital; Consulting Physician to St. Vincent's Hospital, Staten Island; Fifth Vice-President of the National Convention for the Revision of the United States Pharmacopœia; formerly Curator of the New York Botanical Garden. Illustrated; price $3.50 net. Philadelphia and London: W. B. Saunders Company, 1913.

THIS is the latest textbook on materia medica, and it differs in some respects from other books of the kind. In the first place, the author makes no pretence at including every drug that has ever been heard of; he does not even mention all that are included in the United States Pharmacopœia, but makes a selection of those which he believes will be most helpful to the physician in the treatment of the sick. In the next place, the relative space allotted to the various drugs is based upon the author's idea of their relative importance and not upon the number of preparations belonging to the drug. Of course this stamps the book with more of the author's individuality than is sometimes found in textbooks. The discussion on digitalis is particularly good; it is one of the most lengthy chapters in the book. The author seems to have the knack of combining the results of laboratory experience with those of clinical research, and this makes the book more useful to the practitioner. The chapter on alcohol is one of the longest in the volume, and takes up more space than that on digitalis; it is a great help to the modern medical student to be told what is meant by the terms "highball," "cocktail," "milk punch," and "eggnog" (page 302); formerly such information was not obtainable from books, but had to be acquired practically. Tobacco is another topic which occupies several pages; more space is devoted to this drug than to ergot, iron, salicylic acid, the bromides, aconite, phenol, or the iodides.

A COURSE OF LECTURES ON MEDICINE TO NURSES. By HERBERT E. CUFF, M.D., F.R.C.S.; Medical Officer for General Purposes to the Metropolitan Asylums Board; late Medical Superintendent, North Eastern Fever Hospital, Tottenham, London. Sixth Edition. Price $1.25 net. Philadelphia: P. Blakiston's Son & Co., 1913.

WE are not at all surprised to see that this volume is in its sixth edition. Both in the amount of information which it contains, and in the manner of its presentation, this book is a model of what a book for nurses should be. There is no attempt on the part of the author to write a book on practice, but it is assumed that the nurse takes an intelligent interest in her patients and wishes to learn something of the diseases from which they are suffering, and so the author offers an explanation of the symptoms and the object of the treatment. The lectures are on: Germs and infection, use of stimulants in cases of acute illness, feeding of infants, forced feeding of sick children, pulse, inflammation, pneumonia, inflammation of the kidneys, infectious fevers, enteric fever, scarlet fever, diphtheria, measles, whooping cough, bronchopneumonia, paralysis, hysteria, some forms of internal hemorrhage, dropsy, diseases of children, and massage. The author emphatically states that he does not expect nurses to remember all that is in this book, but that he hopes it may serve to increase their interest in their work.

LECTURES ON MEDICAL ELECTRICITY TO NURSES. An Illustrated Manual. By J. DELPRATT HARRIS, M.D. Durh., M.R.C.S.; Senior Surgeon and Honorary Medical Officer in Charge of the Electrical Department, Royal Devon and Exeter Hospital. With 23 illustrations. Price $1.00 net. New York: Paul B. Hoeber, 1913.

THIS is a small volume of less than one hundred pages, well printed in large type, and sufficiently illustrated. The contents are admirably adapted to their purpose, and the author has used the most simple language in his descriptions, and has explained every technical term. The book will be of value to every nurse who is in charge of patients undergoing any form of electrical treatment.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D.; Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Assisted by LEIGHTON F. APPLEMAN, M.D.; Instructor in Therapeutics, Jefferson Medical College, Philadelphia. December 1, 1913. Price $6.00 per annum. Philadelphia and New York: Lea & Febiger.

THIS number contains chapters on diseases of the digestive tract and allied organs, the liver, pancreas, and peritoneum, by E. H. Goodman; diseases of the kidney, by J. R. Bradford; genitourinary diseases, by C. W. Bonney; surgery of the extremities, shock, anesthesia, infections, fractures and dislocations, and tumors, by J. C. Bloodgood; and practical therapeutic referendum, by H. R. M. Landis. All of these contributions are up to the usual high standard of this publication. It is interesting to note in the last chapter that in addition to the comments on the numerous drugs used as remedial agents there are sections on diet, fresh air, and Friedmann's cure; but there seems to be no reference to the radium cure of cancer. Silence is sometimes very eloquent.

## NEW YORK ACADEMY OF MEDICINE.

### SECTION ON SURGERY.

*Stated Meeting, Held February 6, 1914.*

DR. HERMAN A. HAUBOLD IN THE CHAIR.

**Frambesia—Two Cases.**—Dr. CHARLES E. FARR, presented photographs of two patients whose condition had been diagnosed as frambesia, or yaws. The diagnosis had simply been made on the clinical symptoms; no *Spirochæta pertenuis* had been found in the tissues. This disease was very common in the South, but practically never seen in New York.

**Tuberculosis of the Tongue.**—Dr. CHARLES E. FARR presented this patient who had been suffering from pulmonary tuberculosis for two years when a small ulcer appeared on his tongue. It was not characteristic of anything in particular, but might have been actinomycosis, syphilis, or simply a chronic ulcer. As the patient had phthisis it was suspected that it might be tuberculous. The tubercle bacilli were found and the ulcer excised. This condition was not common in the tongue, there being perhaps not more than one-half dozen cases in the city; but nevertheless one should bear the possibility of its occurrence in mind. The patient had had several small nodes in the submental region, but they had subsided.

**Idiopathic Dilatation of the Colon.**—Dr. JOHN F. CONNORS presented this patient, a man forty-three years of age. His family history showed that his mother had died of stomach trouble and his father had died at the age of fifty years from an unknown cause. His present illness had begun six days before his admission to the hospital with vomiting, no movement of the bowels, tense abdomen, tenderness, a fluid wave and shifting Douglas. An enema given one hour after admission returned clear. There was marked distention on the whole left side of the abdomen. The abdomen was opened when something protruded through the incision which was thought to be the transverse colon, but it proved to be the enormously distended colon. The distention extended from the middle of the transverse colon down through the colon. An opening was made at the sigmoid flexure, through which gas and a yellow serous fluid were discharged. Dr. Connors said he had passed his finger down to the rectum and found no obstruction. After operation the patient's pulse was 132, temperature 100° F., and respirtation 30. On the third day an enema was given and there was no return. He was then delirious for four days and there was no return from the enemata during all this time, and no vomiting. The patient had been troubled with this constipation for three years, going sometimes as long as twelve days without a movement. The first time he had vomited was a few days before his admission to the hospital. It was decided to do a resection; this began at the middle of the transverse colon and included the splenic flexure. Since the operation the patient's abdomen was perfectly flat and showed no abnormal signs. The *x*-ray, however, showed that there was still some stasis.

**Multiple Adenomata of the Colon.**—Dr. FRANK C. YEOMANS presented this patient, a young man who had come under his care in August, 1913. He had come from South Carolina, but had lived in New York nine years. His illness began fourteen months before with diarrhea which had recurred from time to time. At the time that he came under Dr. Yeoman's care his bowels acted every hour, blood and mucus were present, and there was great prostration and anemia. The rectum was studded with adenomata which bled on contact. There were many adenomata on the sigmoid and colon. The patient made an uneventful recovery after extensive resection, had gained twenty pounds, and was within six pounds of his normal weight. These cases of multiple adenomata were of rare occurrence. Dr. Yeomans said he had seen one in a child six years of age and one in a man of fifty-six years. Multiple polypi of the rectum and sigmoid were the only conditions to be confused with adenomata, and diarrhea was more characteristic of the latter condition. There was always the danger of the transformation of the adenomata into true cancer, this change being said to take place in 46 per cent. of the cases. Irrigations and a palliative enterostomy produced irritation of the tumors and had to be maintained for a long time. Removal of the tumors singly was difficult and unsatisfactory. The operation might be done in two stages. An enterostomy might be made in the lower ileum. If the condition persisted after long irrigations, implantation might be made low down in the sigmoid.

**Advanced Carcinoma of Inferior Maxilla—No Recurrence in Three Years.**—Dr. GEORGE H. SEMKEN presented this patient. He had first seen the patient September 15, 1910. The etiological factor in the case was not clear. An extensive epithelioma involved a large portion of the lower jaw on the right side and had extended high up in the cheek and along the floor of the mouth as far as the tongue. Externally there was induration of the cheek, lips, and chin. The extensive operation which was performed did not cross the cancer area at any point. The new cheek and chin were formed by flaps from the neck. The internal deficiency was supplied by a flap from the tongue. The patient was out of bed in three days. The cosmetic effect was remarkably good considering the extensive nature of the operation.

**Resection of the Superior Maxilla—No Recurrence in Five Years.**—Dr. GEORGE H. SEMKEN presented this patient, who had been operated on September 15, 1908, for epithelioma of the superior maxilla. The bone was resected from the first molar or bicuspid to the alveolar process. There were no enlarged carotid or lymph glands. There was a slight ptosis of the eye. This might have been prevented by preserving the attachment of the temporal bone to the coronoid process. An other interesting point which he believed the textbooks mentioned was that after a resection made in the usual way one might break off at the palate bone and leave carcinomatous tissue, that was, one might cross the carcinomatous path. He had made a clean excision of the superior maxilla and there had been no recurrence.

**A Case of Strangulated and Gangrenous Obstruction.**—Dr. JOHN A. HARTWELL presented this patient because he illustrated his paper. The man had had cirrhosis of the liver and had been tapped three or four times. Eighteen months afterward he came to him with a strangulated and gangrenous hernia. In the following thirty-six hours seven liters or 7,000 c.c. of normal saline solution were administered under the skin in the pectoral region by means of two hypodermic needles connected with a tank above. The condition of the patient required resection, and an anastomosis was done. There were enormous adhesions, but apparently the cirrhosis of the liver was a thing of the past. There was no general peritonitis, but a terrific local one. The liver was small and there had been no recurrence of the cirrhosis. The remarkable thing in this case was the large amount of fluid that the patient had been able to take by hypodermoclysis.

**A Patient with Unusual Symptoms Cured by Cholecystostomy.**—Dr. EMILY D. BARRINGER presented this patient, a woman thirty-seven years of age, unmarried. Her family history was negative and her personal history showed no serious illness, save some of the diseases of childhood, until the beginning of her present illness. About two and one-half years ago she began to have attacks of persistent vomiting, the first attack lasting five days. The attack was preceded by a headache and was diagnosed as gastritis. These attacks became more frequent and she was obliged to give up one position after another, being subjected to all kinds of diet. During one of these attacks, in September, 1912, she was removed to the hospital, where she was kept under observation for two weeks and her condition diagnosed as pyloric spasm. The attacks were usually preceded by headache and followed some indiscretion in diet. During the two and one-half years before Dr. Barringer saw her the patient had been subject to gastric distention and eructations. She was in one of these attacks when Dr. Barringer first saw her, vomiting violently at intervals of about one-half hour. The abdominal symptoms were negative, the picture being that of an acute gastritis. Four or five hours later the vomiting was still persisting and there was slight tenderness over the gall bladder region. She was removed at once to the hospital for observation, on April 25, 1913. The urine at the time of admission showed traces of albumin, hyaline and granular casts, acetone, and traces of indican. She had a leucocytosis of 15,000 and there was slight tenderness over the gall bladder on deep pressure. The temperature was about 99° F. There was a gradual fall in the leucocytes. Save for the slight tenderness on deep pressure over the gall bladder and very slight rigidity over the right upper rectum there were no gall-bladder symptoms. A test meal showed hyperchlorhydria, but otherwise a normal condition. In view of the violence of the attacks an exploratory operation was advised. The patient was

operated upon on May 6 through a free incision in the right hypochondrium. A careful search failed to reveal anything abnormal save that the gall bladder seemed unnaturally full of bile. It had then occurred to the speaker that possibly these attacks might be connected with hyperdistention of the gall bladder and that by its actual back pressure on the pyloric end of the stomach or the duodenum might cause a partial obstruction. For lack of other findings Dr. Barringer said she felt justified in draining the gall bladder and by a cholecystostomy made it impossible for it to become hyperdistended. This was done. The gall bladder was apparently normal and no stones were found. The patient had a great deal of postoperative nausea and vomiting, but gradually improved and was discharged in the early part of June, 1913. The patient returned to the hospital later with a severe attack of vomiting and in a much weakened condition from ill-advised food. After proper care and a rest in the country she returned in apparently excellent health and had gained twenty-eight pounds.

Dr. W. C. Cramp said he had had a case of tuberculosis of the tongue similar to the one reported. A section was removed and examined and proved to be tuberculosis. The affected area was then excised.

Dr. Herman A. Haubold said that the case to which Dr. Cramp had referred had occurred where he was working with Dr. Cramp. It was well to bear the possibility of this condition in mind, as one might occasionally meet with it.

**Intestinal Obstruction.**—Dr. John A. Hartwell presented this communication in which he described his experimental work in intestinal obstruction in dogs. He stated that this study was undertaken to determine the cause of death following intestinal obstruction. There were three general theories to account for death following intestinal obstruction: (1) The nervous. There was no evidence in support of this theory. (2) The bacteriemic. In testing this theory it had been found by a study of seven dogs in which the blood, liver, and spleen were found sterile in both aerobic and anaerobic cultures that bacteriemia was not a necessary factor in producing death, though it might be a complicating factor. (3) The theory of toxemia, either from food, from secretions, or from bacterial toxins. In order to make a study of food decomposition a series of animals had a complete obstruction produced in the lower duodenum and upper jejunum at varying periods after taking food. The results of this study made it reasonably certain that alterations of food residues in the tract above the obstruction had little to do with causing death. Dr. Hartwell summarized his experimental work as follows: "1. There are two factors at work in producing the symptoms and causing death in intestinal obstruction. First, the loss of water from the tissues, due to excessive drain into the bowel in response to the irritation set up by the retained secretions. This water may be replaced by subcutaneous injection of normal saline solution, and the symptoms caused are thus entirely controlled with the saving of life. Second, the entrance into the circulation of poisonous materials, which occurs only when the mucosa is damaged. This damage results largely from the trauma inflicted by the overdistention acting on the circulation, but possibly also from the chemical action of the digestive ferments stagnated above the obstruction. Such a damage having resulted, there occurs a bacterial invasion into the bowel wall with a death of tissue cells, which is invariably demonstrable by microscopical examination, and in this process the poisonous substances are elaborated. The action of these poisons is apparently not influenced by the administration of saline subcutaneously. The absorption of a poison from any source whatever, as long as the mucosa remains intact, is not a factor. 2. The development of bacteriemia as a cause of death is excluded." The essayist declared that while it was not always safe to transfer the findings of experimental work to clinical practice, and as yet they had not opportunity to apply the teaching of their investigation to the bedside, there were certain applications which seemed justified. It had always been a matter for speculation as to why high intestinal obstruction in man was so much more acute than low obstruction. The explanation was found in the fact that water absorption was entirely stopped in the first, and, in addition, enormous amounts of water were thrown out in the vomitus almost immediately after the obstruction occurred. A rapid desiccation took place, with a severely damaged metabolism, as shown by the deranged urinary output. These conditions obtained much more gradually when the obstruction was low in the bowel. It was a familiar observation that a chronic obstruction might take place in the bowel and progress until the opening was only pin point in size and yet no serious symptoms arise, even though for many days there might be cessation of fecal passage from the bowels. When, however, a complete closure supervened there arose immediately evidence of a severe condition. The explanation of this was found in the fact that so long as gas could escape through the constriction there was no distention of the intestine and hence no damage to the intestinal wall and no absorption of poisonous materials. The stoppage of gas was immediately followed by both these conditions, and unless promptly relieved would result fatally. The practical application of the principles elaborated by the experimental work followed two lines. First, the water extracted from the tissues by the enormous outpouring into the bowel must be replaced. This could be done by means of a continuous hypodermoclysis administered under the skin in the pectoral region by means of needles of the ordinary hypodermic caliber, but longer. In this way the fluid was absorbed almost as rapidly as it entered, two or three liters being given without withdrawing the needles. The absorption would continue until the normal water content of the tissues was reestablished. This procedure had no influence on symptoms resulting from damaged intestinal wall, and hence it was imperative to surgically relieve the obstruction as soon as it was discovered. A second point of practical importance was in regard to the advisability of opening the bowel and, either temporarily or permanently, draining off the contents. Whenever there has resulted from the obstruction any considerable damage to the bowel wall above the constricted point there was danger of serious symptoms arising from the absorption of materials resulting from these changes. Therefore, in the presence of such changes, the more rapid emptying of the bowel through an enterostomy, after relieving the obstruction, might be a wise thing to do. Whether the drainage of the intestine should be made to continue depended on the extent of the damage done. If this was great it was advisable to establish an enterostomy, because there would be some further accumulation of the poisons which would be absorbed unless there was free exit for them. An enterostomy would be necessary if the contents of the bowel above the obstruction were blood tinged, demonstrating a damage to the bowel wall. If the bowel contents were simply fluid feces, the rapidly returning peristalsis, after the obstruction was released, would force the contents onward, and there would be no danger of poisonous absorption when once they reached the normal bowel below the obstruction, because the mucosa here possessed a defense against such absorption.

Dr. W. H. Luckett said that he took issue with the statement that toxic material was not poisonous when it met with the normal mucosa. Perhaps it was not poisonous theoretically, but practically and clinically it was. Hematogenous secretions and toxic materials should be washed out. He failed to see the mechanism which produced the dilatation; it might be increased pressure from within, but it was not from the distention. Dr. Luckett asked Dr. Hartwell if the patient had vomited coffee grounds material. This distention must be manifest for some time before the toxic condition became evident. The case he had intended to present would have been interesting in this connection. He did not vomit coffee grounds material and the stomach pump was used. He then collapsed before there was time for the production of toxemia.

Dr. A. Ernest Gallant said that this confirmed the statement of Warren Robinson, who related an instance of acute dilatation of the stomach after anesthesia. He claimed that the duodenum was clamped between the aorta and the superior mesenteric vessels. He could not understand why the patient had died six hours after if the condition was due to toxemia occurring through the damaged mucosa. That seemed to him to be pretty quick work. Dr. Gallant asked Dr. Hartwell how soon they killed the dogs to find out how many hours it took to damage the mucosa. In these cases the condition was similar to that of cholera and took the water out of the patient very rapidly. The speaker said he could not understand Dr. Luckett's viewpoint. He had seen patients recover so rapidly from their terrible condition, just within a few hours, that there must be something else than the mere poisonous effect on the mucosa. In regard to the question of how to overcome this condition, no one had really succeeded. Opening the stomach itself during gastrostomy had not been successful.

Dr. George Draper said he was not prepared to discuss the mechanical problem, but the hypothesis was in-

teresting. The obstruction had been made with clamps and those devised by Dr. Hartwell were very ingenious and should be a great help. In regard to the bacterial origin of the toxemia, if it were a toxemia, according to their studies no aerobic or anaerobic bacteria occurred in that part of the intestine. Why was the onset so sudden? The onset of bacterial toxemia was usually seventy-two hours. With regard to the giving of water they had tried it in only a few cases, about twelve, and had not given as much as Dr. Hartwell gave. They had tried pylocarpine and the animals lost weight at about the same rate as in intestinal obstruction. There were no symptoms to show that the loss of water was producing a change in metabolism. The pulse was the same, and this was not the case in intestinal obstruction; in this condition there was something more than mere loss of water. They had found that dogs in which obstruction had been produced lived longer when fed on the watery secretion of epithelial cells. There might be a bacterial element in the toxemia, but he predicted that the cause would be found in the biochemical enteric situation.

Dr. Angelo L. Soresi said he wished to call attention to the effect of traumatism on the mucosa. In grafting experiments with mucosa he had used iodine on the mucosa and the experiments had failed because of the iodine. If the gut was milked to remove feces the dog died or was very much sicker in comparison with dogs handled gently. Injury to the mucosa caused trouble.

Dr. Alexis V. Moschcowitz said that in rather a large experience with intestinal obstruction he had found it advisable never to perform an enterostomy when he could establish the fecal current at one operation. When a primary operation was possible the results were infinitely superior to enterostomy. Another point about which he wished to speak was that while the theory advanced by Dr. Hartwell was very interesting it did not quite explain the symptoms of intestinal obstruction. Dr. Moschcowitz said he had no substitute for the theory, but he had had cases of complete obstruction in which the patient was not as sick as in those cases spoken of in which there was no interference with the circulation. He recalled having operated on an enormous volvulus of the sigmoid; it was as thick as the thigh of an adult and measured thirty-two inches in length, and the patient was not sick at all.

Dr. John A. Hartwell said he was speaking of intestinal obstruction and the references to acute dilatation of the stomach had no bearing on the subject. One could produce obstruction of the pylorus in dogs and they would be in no worse condition than though their tails were cut off. As to Dr. Luckett's question, he thought the distention was actually from pressure from the inside. When there was no damage to the mucosa the dogs were not sick, and when the mucosa was damaged they were sick. Whipple had found the same thing. They rarely got a black hematogenous vomitus. If the fluid passed on there was no danger below the seat of obstruction. Dr. Hartwell agreed with Dr. Moschcowitz that an enterostomy was a bad thing, but occasionally one had to resort to it. His experience had not been absolutely discouraging. The point made by Dr. Draper in regard to the rôle played by biochemical processes was well taken. In doing a double occlusion marked and active bacterial growth had been obtained from the part of the intestine removed. When the dogs died soon they had always found this explained by the damage to the mucosa, and when the dogs did not get very sick there was no, or very little, damage to the mucosa. They had found that the dogs were sicker when the obstruction was higher up in the intestines than when it was low down.

**Nonreducing Operations for Fracture.**—Dr. William Darrach, after reviewing the indications for nonreducing operations, gave a lantern slide exhibit showing the results of nonreducing operations in a number of cases in which he had operated.

Dr. A. J. Brown said that Dr. Darrach had brought up an important subject which was well worth serious discussion. From the points brought out by Dr. Darrach it seemed that his object was to obtain function rather than to remedy the deformity. In taking away bone one should exercise great care in regard to the muscles, tendons, and ligaments that the limb might be brought into correct anatomical relation with the remainder of the body. Dr. Brown suggested that in operations on the ankle lengthening the tendo Achilles to the anterior lip of the tibia, thus making it possible to get more than 10 or 15 degrees flexion.

**Primary Carcinoma of the Liver.**—Dr. Frank C. Yeomans presented this specimen. The patient, a man thirty-seven years of age, was operated on in 1906 for carcinoma of the liver. They would probably say that if it had been carcinoma of the liver the patient would not be alive. In 1913 he had attacks of severe pain after an injury and a growth was found on the site of the old scar. He was operated upon the second time November 14, 1913, and a tumor the size of a grape fruit was found attached to the old scar tissue of the liver. The patient died an hour after the operation. The carcinoma, which was seminecrosed, was exhibited. In the report of nine cases of primary carcinoma of the liver which had been operated upon three had died at the time of the operation or soon after.

SECTION ON OBSTETRICS AND GYNECOLOGY.

*Stated Meeting, Held February* 24, 1914.

Dr. Asa B. Davis in the Chair.

**Pregnancy Complicated by Typhoid Fever with Hemorrhage and Relapse; Delivery at Term; Report of the Bacteriological and Serological Findings in Mother and Child.**—Dr. Samuel Berkowitz made this report. He said that in two-thirds of the cases of pregnancy complicated by typhoid fever, the fetal prognosis was grave on account of abortions, miscarriages, or premature deliveries (Liebermeister) caused by the toxemia (Sacquin), or the hyperpyrexia acting as an insolation upon the fetus (Runge). These two conditions also tended to produce uterine hemorrhage, separation of the placenta, nephritis, and hyaline degeneration of the uterine musculature, as well as asphyxia and death of the fetus with the induction of labor. The patient was thirty-one years of age and was admitted to the Beth Israel Hospital toward the end of the first week of the typhoid fever and about five months pregnant. The disease was moderately severe and was complicated by an intercurrent relapse about the end of the third week of her illness and an intestinal hemorrhage about a week later. Forty-eight hours after admission the uterine souffle was heard and one day later the fetal heart sounds. One month after discharge the patient was again admitted; she was in labor, and in a few hours a full-term normal baby was delivered. Cultures were made from the placenta and the tissues stained for typhoid bacilli; also cultures were made from the placental blood and from the cord with negative results. The mother's blood, which had been positive during the illness, was now negative for the Widal reaction. The same result was obtained on examination of the child's sera and the mother's milk. The stools of the mother and child were negative for typhoid bacilli. Ten days after delivery the mother and child were sent home. They were under continued observation for eighteen months and found to be in excellent condition. Foulkrod contended that the severity of the disease was intensified by pregnancy up to the fourth month, but mildly so after the sixth month. According to Lynch typhoid fever was more often seen during the first half of pregnancy. Only eight out of twenty-six cases reported in the literature, or 30.6 per cent., gave a positive agglutination reaction (Brickner and Oppenheimer.) In the treatment of this condition the danger to the mother should be considered as the indicataion for interference.

Dr. Asa B. Davis recalled three cases of pregnancy complicated by typhoid fever with hemorrhage, two being operated on. Toxemia was undoubtedly present in these cases. In many of these instances the fetus was very feeble, and this toxemia resulted in death. The induction of labor, unless forced upon one, should be avoided. The operation was not a simple one and should not be performed except for good reasons because of the added strain upon the mother.

**Tænia Saginata in the Appendix.**—Dr. M. Caturani presented this specimen, which consisted of an appendix in the lumen of which were two living segments of tænia and corresponding eggs. The appendix had been removed during an operation for a pelvic condition. The patient was an Italian woman, thirty years of age. Infection had followed her first childbirth seven years ago, and a few months afterward she had been subjected to an operation. The left adnexa were removed and as a result the patient developed hernia on the line of the abdominal incision. Dr. Caturani said he had operated on the patient for the hernia on February 4, 1914, at which time he freed the uterus from adhesions and removed the right tube and a small myoma which was imbedded in its wall. The uterus was suspended. The appendix,

which was retrocecal and covered with adhesions, was removed as a routine measure. The appendix was relatively long and showed a wide opening at the base. At the touch something strange could be detected at the lumen, which proved to be a tænia; another segment, easily displaceable, was brought toward the apex and out through a small opening made in the wall. The patient reluctantly admitted that she had noticed frequent emissions of segments of tænia in the feces during the past three years. She had never had any real appendicular attack. In a similar case reported by Robb the patient had been operated on for tuboovarian abscess, not for appendicitis. It seemed that the presence of this kind of worm in the appendix did not affect the organ. Examination showed a slight chronic inflammation of the structure of the appendix and lymphoid hyperplasia. The examination of the two segments removed from the appendix, as well as of many others, showed that this tænia was the *Tænia saginata*.

**Carcinoma of the Body of the Uterus in an Eighteen-Year-Old Patient.**—Dr. HERMANN GRAD reported this case. At the age of eighteen she was admitted to the hospital and it was thought that she had either a polypus or a submucous fibroid. A hysterotomy was performed and there was found a large mass of soft material villous in structure. After a curettage and the removal of an ovarian cyst the wound was closed. The pathological report was carcinoma of the uterus. For three months the patient did not menstruate.

Dr. HERMAN J. BOLDT said there was a true transitional stage in these cases of typical carcinoma of the body of the uterus. He believed that these cases should be operated upon and in a radical manner.

Dr. ROBERT TILDEN FRANK asked Dr. Strong regarding the pathology because he did not catch the pathological differences found. The extreme youth of the patient was interesting.

Dr. L. W. STRONG said that he might well come under criticism for the opinions that he had expressed in Dr. Grad's case if one did not consider that in the case of the curettings he had no means of judging how the basal glands were acting, that was whether they were invading the myometrium or not. The appearance of the curettings was that of a destructive adenoma; the cells were in several rows with some grade of optical unrest and mitosis. These things did not in themselves invariably constitute carcinoma, but it was by their grade of intensity that one judged. When, however, the entire uterus was seen it was found that the glands were not invading, or at the most only superficially, much as an adenomyometritis invaded. It was found that the basal glands were of a simple type and that many had a low columnar epithelium due to their distension into cysts. The whole mucosa was tremendously hyperplastic, villous, and macroscopically presented the picture of adenoma destruens. The microscopic picture showed that the diagnosis must be adenomatoid hyperplasia of the endometrium, which of course was not malignant.

Dr. GRAD closed the discussion and said that the carcinoma might have been due to ovarian irritation. There was no doubt but that the patient had a malignant neoplasm. There was much bleeding and she was losing strength. After the curettage she gained in weight. There was no doubt in his mind regarding the surgical aspect of the case. He believed that the girl would remain well.

**Vaginal Fixation, or Interposition Operation for Prolapsus Uteri.**—Dr. HERMAN J. BOLDT presented these specimens, which consisted of parts of the corpus uteri and the cervix removed in doing a vaginal fixation, and said that he had seen several cases during the last few months in which the operation had not been as satisfactory as the patients had been told they would be. He attributed this to the omission on the part of the surgeon who did the operation to excise a wedge-shaped piece of the body of the uterus, and to do a high amputation of the cervix, thus reducing the size of the organ. By these measures a good result would many times be procured which would not otherwise be possible. These parts of the operation were important unless atrophy of the uterus had already occurred. The proper repair of the pelvic floor was also very important. Dr. Boldt stated that the pathologist's report verified his position. One of the specimens sent to the pathologist consisted of the cervic uteri and the other of many pieces of tissue, uterine scrapings, and a piece of the uterine wall, showing the peritoneal covering and mucosa. In both specimens the mucosa was very much thickened and the glandular elements showed marked hyperplasia. The myometrium showed hyperplasia of the connective tissue, chiefly in the intima of the thickened walls of the blood vessels. The diagnosis in both cases was chronic metritis. Dr. Boldt said that the steps in the operation as practised by him when the uterus was large and bulky were as follows: After thoroughly divulsing the cervix, a longitudinal incision was made of the anterior vaginal wall from just beneath the meatus of the urethra to the cervical junction of the vagina, and a transverse incision of the vagina at its insertion to the vaginal part of the cervix. The anterior wall was widely separated from the bladder and there was complete separation of the bladder from the cervix, bringing the body of the uterus well out into the vagina. A sufficiently large piece of the uterine body was then excised and the wound closed with two rows of interrupted chromicized catgut sutures. If the patient was still menstruating she was sterilized by exsecting the uterine cornu, closing these wounds, and tying the uterine ends of the tubes. A high amputation of the cervix was done covering the raw surface with the vaginal mucosa, after a ligature had been placed on each of the broad ligaments. After pushing the bladder into the peritoneal cavity and holding it out of the way by fastening the fundus of the uterus well forward in the vagina, the sutures for fixating the uterus were put into position, using interrupted catgut; then as much of the superfluous vaginal mucosa as necessary was removed. The sutures were then tied. Finally, the pelvic floor was built up by exposing the levator muscles and bringing them together with three interrupted kangaroo tendon sutures, or heavy iodinized catgut. The perineum was built up higher than normal.

**Microphotograph from a Case of Chronic Metritis.**—Dr. BOLDT showed this microphotographic section, which had been made from a patient who had been bleeding for about two years and had been told by two physicians that her uterus required removal. The condition shown was variously called metroendometritis, fibrosis uteri, and hyperplasia uteri. From a strictly anatomical point of view the term chronic metritis was the nearest correct, but all of the names represented the same condition from a pathological point of view. It was Dr. Boldt's opinion that such patients could be cured of their metrorrhagia by other methods than removing the uterus. Carbolic acid or chloride of zinc, as he had described on other occasions, would positively cure nineteen out of twenty of these cases. The patient had not been bleeding for three weeks, whereas, previously the bleeding had been nearly constant. The pathologist's report described the specimen as a flat, grayish, firm, fibrous-like piece of tissue, three by two cm. in extent, and not remarkable in the gross. The microscopical examination showed a mild degree of acute inflammatory reaction associated with a considerable necrosis of the interglandular stroma. The histological elements of the endometrium that could be definitely studied showed no particular pathological change. The glands were only moderately numerous and their epithelial cells were normal throughout except that they stained poorly. There was no evidence of malignancy, but a moderate degree of fibrosis with arteriosclerotic changes.

Dr. HERMANN GRAD asked Dr. Boldt if the wedge removed was from the anterior or lateral aspect of the body of the uterus. He was surprised to learn that the body of the uterus diminished in size and there was no doubt but that the patients did better after this operation. In those cases in which the uterus was heavy he advised bringing the uterosacral ligaments forward and shortening the round ligaments. He had performed twenty-two of these operations with success.

Dr. BOLDT, in reply to Dr. Grad, said that the wedge-shaped piece was taken from the anterior portion of the body of the uterus because this was the part in direct contact with the vagina. He made a long section which was easily closed.

**The Clinical Significance of Sarcomatous Changes in Uterine Fibromyoma.**—Dr. SAMUEL HERBERT GEIST read this paper. He stated that it was his intention to define some indications for the use of the Roentgen rays and radioactive substances in the treatment of uterine fibromyomata. In the study of three hundred and sixteen cases of uterine and cervical myomata he had found that sixteen showed sarcomatous changes of various types. He pointed out the difficulty of making a clinical diagnosis before operation and also a macroscopical one at the time of operation. The clinical histories in his sixteen cases showed nothing characteristic

upon which a diagnosis of malignancy could be based. The macroscopical appearance of the tumor in only two cases suggested malignancy to the surgeon. The author mentioned that other investigators had only made the diagnosis of sarcoma after recurrences had taken place. It was also pointed out that the ages of the patients ranged between thirty-four and sixty-one years; the occurrence of the condition was most common about the time of the menopause. *X*-ray treatment, while it might favorably influence the size of the tumor, did so in all probability by its action on the ovary, and although the hemorrhage might cease and the growth diminish in size there was, in patients at this age, the danger of leaving behind a potentially malignant tumor. In a number of cases, after supravaginal amputation, recurrence had taken place in the pelvis and most commonly in the cervical stump. Occasionally after a panhysterectomy recurrences had arisen and for this reason the author urged the advice of a competent pathologist at the time of operation, and a panhysterectomy, with liberal resection of the broad ligament, if a diagnosis of malignancy was made. The proper treatment in women at the time of the menopause, with fibromyomata giving rise to symptoms, was operative.

Dr. W. L. Strong said that Dr. Geist's paper suggested a number of points of rather a controversial nature in regard to the histogenesis and classification of these tumors. Meyer and others would not admit that a sarcoma could arise from a mature cell and would not put weight upon the origin from blood vessel musculature. In the opinion of many authors the sarcoma was a sarcoma from its very inception, and did not arise from a changed muscle cell, but from an embryonal cell of connective tissue origin. Many tumors had been diagnosed in the past on the basis of tracing gradations from normal cells to tumor cells. But tumors grew entirely by multiplication of their own cells and not by the transformation of normal cells, nor was a tumor cell of a myoma transformed into a sarcoma cell. The only safe criterion for the diagnosis of sarcoma of the uterus was infiltrative and destructive growth; mere richness in cells, mitoses, and even irregularities in size of cell, did not constitute sarcoma.

Dr. Robert Tilden Frank said that he agreed with Dr. Strong in the statement that it was the opinion of many authors that sarcoma was a sarcoma from its very inception, and did not arise from a changed muscle cell. It arose from an embryonal cell of connective tissue origin. Several men might be given portions of the same specimen of sarcoma of the uterus and there would be received diametrically opposite reports of their findings. The reports regarding recurrences differed, some giving from one to seven, others from one to ten. There were very few men who were able to report one, two, or three, of the cases seen during the course of many years. As to the value of the *x*-ray, he feared the man who was not trained in its use. If the tumor was small it should be treated tentatively, but if large it should not be treated so. The difference in the mortality rate between supravaginal and complete hysterectomy was not very great.

Dr. Herman J. Boldt said that very often when the tumors were examined a second time a large number of them would be found to be malignant. In many instances amputations were done for supposedly benign tumors which subsequently were found to be malignant. He had seen probably ten or twelve cases where a supravaginal amputation had been performed, recurrences had followed, and the patients died. Supravaginal amputation he preferred because, as a rule, it left a better roof of the vagina. If there was an eroded cervix he did a panhysterectomy.

Dr. Herman Grad referred to the statistics regarding sarcomatous changes in these cases of uterine fibromyoma, and called attention to a paper of Dr. Graves of Boston which was read in 1905, in which it was stated that of thirty-five cases examined three had sarcomatous degeneration. If the fibroid was large and palpable and gave pressure symptoms it was his custom to operate. But if the tumor was small he gave other than operative measures a trial. The supravaginal operation upon these fibroids was a simple operation and gave a low mortality. Two questions of import were not clear in his mind: In what percentage of cases did malignancy occur? In what percentage of cases did myocardial changes occur? They did not know whether or not these fibroids produced myocardial changes.

Dr. Samuel Herbert Geist said that in a recent article it was clearly shown that muscle cells were present in sarcomata. What was found depended largely upon the man at work. The fact that many of these cases were overlooked and not diagnosed showed that the men had a tendency to err on the wrong side.

---

## MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK

*Stated Meeting, Held February* 16, 1914.

The President, Dr. Reynold Webb Wilcox, in the Chair

**Address of the Retiring President.**—Dr. Reynold Webb Wilcox, the retiring president, made a short address, in which he spoke of the satisfactory manner in which the purposes for which the association was organized had been carried out. During the ten years in which he had served as an elected member of the Council and during the four years of his presidency, he said, a very high standard of scientific work had been maintained and absolute harmony had prevailed in the society, and he trusted and believed that the same conditions would continue to characterize its history. He then introduced the president-elect, Dr. Thomas S. Southworth.

**Resolution on the Retirement of Dr. Wilcox.**—Dr. P. Brynberg Porter, the recording secretary, presented a resolution on the retirement of Dr. Wilcox, which was seconded, with eulogistic remarks, by Dr. Thomas Darlington, chairman for the Borough of Manhattan, and unanimously adopted.

**Address by the President Elect—Some Observations on the Child of To-Day.**—Dr. Thomas S. Southworth, the president elect, said that many factors had contributed to the increased attention at present paid alike by the parent, the humanitarian, and the State to the preservation and expansion of child life. In the city of New York alone there were now no less than 924 agencies whose activities were correlated through the Child Welfare Committee. This movement for the child was the more significant when we considered that it was really only in its beginning. The magnitude of the beneficent results which would eventually be accomplished it was as yet impossible to foresee. Besides the invaluable services rendered as advisors to other branches of the work, our profession had been eminently progressive in the more circumscribed field of medical endeavor. Allowing for the differences in the incidence of disease in infancy, youth and adult life, every advance in general medicine was carefully scrutinized, tested, and adapted for the benefit of the child. The problem which had most immediately engaged the attention of the pediatrist was that of nutrition after the birth of the child. Under careful scrutiny and a vast amount of laboratory and clinical investigation, the old haphazard empiricism of artificial feeding of infants had given way to the acceptance of certain fundamental principles which were brought into play as the necessities of each individual infant indicated. The former hard-and-fast methods had been replaced by a series of useful measures, each with its scientific basis, which might be employed upon the appearance of definite indications and in accordance with the experience and judgment of the physician. Owing to the realization that the inherent biological differences between the milks of different species made these artificial measures at times ineffectual, there happily had arisen coincidently all over the civilized world a fuller appreciation of the importance of a mother's nursing her child. As might have been expected, the first outcome of this movement had been the demonstration of the fact that a far larger proportion of mothers were able to nurse their babies, wholly or in part, than had previously been considered possible; and this had further led to the desirable concentration of attention upon the problem of so improving the health, nutrition, and hygiene of the mother as to restore an additional number to the ranks of those able to nourish their offspring. There was still, however, a tendency, even in the medical profession, to undervalue or neglect partial breast-feeding. In our institutions for young children it had taken many years to impress the life-saving value of partial breast-feeding, but it was now a matter for congratulation that in some of them paid wet-nurses had been secured, and that in Boston and in Bellevue Hospital here the purchase of drawn breast-milk from needy women had been established upon a fair commercial basis. While attention had been sharply focussed upon the feeding

of the child during the first two or three years of life, the diet of the child from three to ten had received comparatively little consideration. With the passing of the traditional period of anxiety for the first summers on a mixed diet, vigilance was relaxed, and, under the guise of a needful variety, the child was allowed a range of articles which was at variance with the simple primitive needs of a normal, growing young animal. With the dietetic bars down, digestive disturbances crept in which in earlier years had been scrupulously avoided, and the appearance of the child of six or seven belied the promise he had given at three. Then, again, too many unnecessary and often ill-advised pleasures were apt to be forced upon the child, and the complexity, extravagance, and even rather doubtful nature of some entertainments arranged for children not only stimulated them unduly, but had been found to encroach too much upon the hours which should be given to study, rest, and healthful outdoor exercise. A timely protest had just been registered by the formation in this city of the Parents' League, which aimed at a rational abatement of these conditions. In all populous communities the opportunities for exposure to infection were manifold. Possibly one reason why the circus and similar gatherings were the greatest exchanges of germs was because few except the most intelligent parents could bear to leave at home the child who showed some symptoms of beginning illness on the morning of a long-promised treat. Then, too, there was the temptation to the parent to enjoy the child's pleasure in the sights of the crowded shops, unmindful that such a passing pleasure might be too dearly paid for if there he contracted the contagious cold so widespread during our autumn and winter months. Habits were easily formed in childhood, and bad habits, such as the sucking of fingers, were readily checked at the start, before they had taken root in the subconscious self. Aside from their unseemliness, the potentialities for evil from them were very great. Why guard the child with quasi-sterile and aseptic measures, and yet allow the dust and dirt from everything he touched to be transferred by moist fingers to his mouth, with ever-present danger of infection? Many rather absurd contradictions arose in the effort to give expression to the modern solicitude for the health of children, and some of the most glaring appeared daily among the important side issues of the milk question. In view of the proven risk from bovine tuberculosis and other ills of bacterial origin, the use of a certified or at least pasteurized milk had become a fixed rule in all thoughtful families, yet one constantly found the same parents giving butter of unknown origin to their children, in blissful ignorance of the findings of Hess that tubercle bacilli, as well as other harmful bacteria, were found in larger relative proportion in butter than in the milk from which it was made. With equal carelessness, junket was made for children from ordinary, dubious milk, while the ice cream served them was often, both in its origin and composition, the despair of the pure food expert. Having referred to the danger attending the wearing of the short stocking or sock except in warm weather, Dr. Southworth went on to say that in no respect perhaps had the attitude toward the child changed more completely than in the school. New methods, a human interest, shorter periods, more interesting presentation of the subjects, alternation of lighter with harder work, fresh air, and hygienic exercise under the guise of recreation had now made the act of learning an enjoyment, instead of an irksome task. All honor was due those pioneers in modern education who had cast off the bonds of tradition and opened the way for vocational training in our schools. Necessary as were the fundamentals in education for all children, early or late there came a point where instruction was best differentiated for their present and future needs. Since instruction in the family had vastly decreased, special instruction was imperative for the schoolgirl if she were to take her natural place in the home ordained to failure. Might we not have happier and less extravagant homes, less divorce, less vague seeking for a mission in the market-place, if the girl's education always fitted her to perform her functions in the world with less groping and less drudgery? In the world of efficient business men learned their trade before full responsibilities were thrust upon them; should it not be thus with the women and the mothers who were to be? Well might our satisfaction be great with what had been accomplished and what had been begun for the child in our day and generation, and great our confidence in the survival only of the best; but, with all our advances, we were yet far from the day which would see the eugenic superman outnumber his less fortunate brother. Insistent nature would often thwart our higher purposes, and it was given to us to aid her progress chiefly by removing from her path the unnecessary obstacles of man's making.

**The Value of Cocaine in Disturbances of Metabolism.**—Dr. William H. Porter, in this paper, said that unless cocaine was chemically pure it might contain some of the two highly toxic alkaloids found in erythroxylon coca, one of which, isatropyl-cocaine, was a decided heart-muscle poison. The varying results where cocaine alone was used, and the sudden development of toxic symptoms frequently described, might be due to preparations containing these impurities. Personally he had never seen any one develop toxic symptoms when cocaine was being used internally. It was not the purpose of the paper to consider the local effects or the hypodermic administration of cocaine in connection with surgical operations, but to deal exclusively with its effects upon the system and show its value when administered by the mouth, as internal medicaments were, in profound disturbances of metabolism. While all were familiar with the great value of cocaine used hypodermically or by direct local application, its great power for good in connection with the large field of internal medicine, he was convinced, was not so fully understood as it should be. This assertion was based upon his personal observation and use of cocaine in hundreds of cases, which had presented all forms and kinds of metabolic disturbances, both acute and chronic. Both historic and experimental evidence seem to prove conclusively that this substance has the power to augment forcefully almost all the physiological activities of the animal economy, and this not only for a short time, but to sustain these augmented functions for a considerable period; so much so that the working power of the system is materially enhanced. The effect of cocaine when given internally within its physiological limits, as all therapeutic agents were supposed to be when administered scientifically, was to stimulate first the cerebral hemispheres, next the medulla, and afterward the spinal cord. It lessened fatigue, and to a certain extent augmented both mental and muscular activity. The respirations were increased, and the muscular contraction of the heart was slightly quickened and also increased in force. There was a slight rise in blood-pressure, and the augmentation of both the respiratory and circulatory activity enhanced the reduction processes of the body, a highly essential requisite in defective metabolism. Thus, it quickened intestinal peristalsis and also alleviated abdominal pain; effects naturally tending to improve digestion and the absorption of food products. Glandular activity in general was slightly augmented and the temperature slightly raised, and all this occurred without any perceptible change or specific symptoms noticeable by the subject. With such results as these, it was not to be wondered at that the native Peruvians felt that they could endure more and were stronger for chewing the leaves of the coca plant. On the other hand, cocaine, like all other alkaloids and glucosides possessing stimulating properties, when it was pushed beyond a certain point depressed or arrested the physiological activities which it had at first augmented. Cocaine seemed to excite all the functions of the body more uniformly than any other known alkaloid. Hence its greater value in disturbances of metabolism, and this was probably the reason why it caused improvement in all the patient's symptoms when all other measures at our disposal had failed. So long as the dose was kept well within the physiological limit, only good would result, but beyond this limit bad results must follow, as was the case with all foods and therapeutic agents when pushed beyond such limit. An interesting point in connection with cocaine was the fact that patients who are profoundly depressed by it when applied locally (possibly through reflex over-stimulation), can take one and two grains of it internally three times a day, not only with no untoward effects, but with highly beneficial ones. From the observation of several instances of this kind the speaker had concluded that the local and the internal effects of cocaine are entirely different and must be studied separately. There was something entirely different, he said, in its peripheral reflex stimulation and its oxidation reduction within the body. To fully understand what was meant by this observation reduction process, as applied to therapeutic agents, necessitated first a brief study of what happened to normal foodstuffs in their transit through the animal economy. With a clear appreciation of this, much of the mystery in connection with the action of our therapeutic agents was eliminated, and they fell easily into a class of food

products, though of higher chemical activity than the ordinary foods. It was now well established that all food substances acted along one of three or four different lines: (1) All inorganic substances were solvents or mechanical irritants; (2) they acted as mechanical irritants by multiplication or division of the molecules before they were finally reduced to less complex compounds; (3) they underwent direct oxidation reduction —applicable to all simple, reducible substances, like the starches, sugars, and fats, by which process there was evolved simple caloric force with which to energize all the chemical and physiological activities of the animal economy; (4) they underwent a peculiar isomeric change, or rearrangement of the atoms, as a result of which, while there was no change in the number of the atoms, there was a wide difference in the appearance of the molecule, with a radical difference in its actions. Now, when we came to analyze the action of cocaine, or any of the oxidizable alkaloids or glucosides, we found the same conditions or chemical laws controlling their transit through the body. When such substances were undergoing this oxidation reduction there was evolved a certain amount of caloric force, just as in the case of all foodstuffs. Primarily the amount of caloric power was in direct proportion to the amount of oxygen consumed, but with all substances the law of mechanical irritation and the effects of isomeric transmutation had also to be taken into consideration in appreciating their full action. It was quite probable that it was in these isomeric transmutations, and not alone in the heat production caused, that we had the explanation of the peculiar train of symptoms and intensive activities resulting from the internal use of alkaloids. It should always be remembered that the rapidity with which the transmutations were brought about was largely responsible for the severity of action observed. In some instances, as in the case of aconitine, the amount which could be taken was very small, while with other alkaloids, such as cocaine, much larger quantities could be administered before any perceptible effect was produced or before the physiological limit was passed and the toxic stage reached. The comparatively large amount of cocaine which could be taken and the slowness of its transmutation might perhaps account for its decided uplifting and sustaining power. To suppose that it could in any sense take the place of normal food products would be absurd, but all the evidence went to prove that, in conjunction with a well-regulated diet, it greatly assisted in the perfect utilization of the food, and in a remarkable manner. It stimulated and excited the sluggish masses of protoplasm into activity when all other measures failed to do so. In health, under its influence, one could endure with greater mental and muscular strain, especially the latter. It should not, however, be used in health, for under ordinary circumstances it was not required. This rule was one which, when the physiological economy was entirely normal, should be applied to all highly stimulating substances, yet it was a well-known fact that throughout the ages mankind had always sought, found, and used some more stimulating substance than ordinary food, and probably always would. In all disease processes, and in all profound disturbances of metabolism, in which the normal foodstuffs were no longer capable of exciting into physiological activity the protoplasmic masses of the economy, when everything was at a standstill, as it were, or when it became apparent that the patient was steadily losing ground, the addition of half a grain or more of cocaine three times daily had, in a large number of instances under Dr. Porter's observation during the past twenty-five years, produced almost miraculous changes for the better, even in cases which seemed almost hopeless. In all chronic affections its power for great good could not be over-estimated. For the last ten years he had employed it more and more in the acuter diseases. When it was given early in pneumonia, and throughout the attack, the results obtained had convinced him that the chances for recovery in this disease were greater than without its administration. The same might be said of all acute affections, for if it had the great sustaining power which all the evidence seemed to show it possessed, the ability to eliminate the toxins of disease must be markedly augmented by it. Although he had prescribed cocaine extensively for nearly thirty years, he had yet to see the first instance in which the patient had acquired the so-called cocaine habit as a result of its internal use. Therefore, in his judgment, cocaine was a very valuable remedy in connection with internal medicine, and one which had not received the attention it really deserved. In closing, he stated that he usually gave it in combination with caffeine and strychnine. If the criticism were made that when a remedy was used in conjunction with other substances, one could not judge accurately as to its true value, he would refer to the emphasis which he had placed on the improvement following the use of cocaine when all other known remedies had failed. This, to his mind, was the highest test for any remedial agent. The discriminating mixture of several alkaloids in one prescription by the scientific physician, who knew the exact chemical composition of each and just what each would accomplish alone and in combination, he believed to be a decided advantage.

Dr. Ransford E. Van Gieson said that he had employed cocaine internally for the past ten or twelve years, and with excellent results. He had given it in small doses, a quarter of a grain three times a day, usually in combination with nux vomica. He had never observed any tendency whatever to the formation of a drug habit, and believed that Dr. Porter was entirely right in his assertion that the internal administration of cocaine did not beget such a habit.

Dr. Porter stated, in answer to a question, that he almost invariably gave cocaine in capsule form. The beneficial effects of the drug, he believed, were due chiefly to the isomeric change after its ingestion to which he had referred in the paper.

BACTERIOLOGY.

1. Name the important pathogenic diplococci.
2. Define the following terms: (*a*) germicide, (*b*) antisepsis, (*c*) asepsis, (*d*) sterile, (*e*) disinfectant.
3. What is essential to the life of bacteria?
4. Give method of staining cover glass preparations.
5. Give in detail a method of staining tubercle bacilli in fluids.
6. By what laboratory methods may rabies be diagnosed?
7. Give details of examination of suspected urethral discharge for gonococci.
8. What is infection?
9. Name five culture media.
10. (*a*) Describe the Klebs-Loeffler bacillus and (*b*) how would you stain it?

PATHOLOGY.

1. What are the pathological changes in appendicitis?
2. What are the structural changes in the various types of cirrhosis of the liver?
3. What are the causes of stricture of the esophagus?
4. (*a*) What changes take place in progressive muscular atrophy? (*b*) What is the cause of the changes?
5. Give the pathology of arteriosclerosis.
6. What lesion of the brain and spinal cord would you expect in a syphilitic in the tertiary stage?
7. Differentiate between the sounds of an acute pleurisy and acute bronchitis that you would expect to hear with your ear against the chest walls of a patient.
8. If you were given a specimen of pus and asked to determine the identity of the organism that caused its production, give some of the details as to how you would proceed.
9. (*a*) What lesion do you consider most characteristic of typhoid fever? (*b*) Describe it.
10. (*a*) What is a sequestrum? (*b*) How are sequestra formed?

OBSTETRICS AND GYNECOLOGY.

1. What is the hygiene of pregnancy, and what advice would you give a pregnant woman from an hygienic standpoint?
2. How would you differentiate between pregnancy and ovarian tumor?
3. (*a*) Describe an eclamptic attack, (*b*) give premonitory symptoms.
4. (*a*) How would you manage inevitable abortion? (*b*) Give some of the dangers of an abortion.
5. (*a*) How soon after the birth of a child would you

ligate the umbilical cord? (*b*) How would you ligate and dress it?

6. (*a*) What indication would induce you to insert your hand into the uterus during or after labor, and (*b*) what precautions would you observe?

7. What are the dangers in the use of forceps in delivery, and how are they avoided?

8. What care would you give the mother after labor?

9. What is phlebitis and how would you guard against it while managing a case of labor?

10. Give the symptoms and treatment of mammary abscess.

## ANSWERS.

### BACTERIOLOGY.

1. The *important pathogenic diplococci* are: The diplococcus gonorrheæ, diplococcus meningitidis, and diplococcus pneumoniæ.

2. *Germicide* is an agent which kills microorganisms.

*Antisepsis* is the inhibition of the growth of microorganisms.

*Asepsis* is the absence of microorganisms.

*Sterile* is the condition of a substance when all microorganisms have been killed or removed.

*Disinfectant* is an agent which removes or kills infectious microorganisms.

3. *Essentials to the life of bacteria:* Most bacteria require proper temperature, generally at or near that of the body; oxygen is generally needed, those that cannot live without it being called aerobic, and those that can grow without it anaerobic; nutriment of a proper kind, containing both organic and inorganic materials; a slight degree of moisture; a medium of slightly alkaline reaction, and rest. Individual bacteria may require modifications of the above essentials.

4. Cover glass preparations may be stained by Ziehl's carbolfuchsin method, Gabbett's method, Gram's method, or Loeffler's method with methylene blue. (See QUESTIONS 5 AND 7.)

5. The fluid must be centrifuged for a long time. Some of the sediment is placed on a slide with a small quantity of egg albumin; it is covered with some carbolfuchsin, and allowed to steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin, red rods, while all other bacteria will appear blue.

6. "Rabies may be diagnosed in an animal by observing the course of the disease, by autopsy and by inoculation of test animals and observation of the course of the disease in them. If the suspected animal be caged, the question of rabies may be settled in a few days, for, if he is mad, the raging stage will be quickly followed by the characteristic paralysis and death. If the animal has been killed, a careful autopsy may reveal the absence of food from the digestive tract and the presence there of abnormal ingested material (grass, wood, or stones), highly suggestive of rabies. Microscopic examination of the central nervous system may reveal the Negri bodies, characteristic of the disease. For confirmation of the diagnosis a portion of the brain or spinal cord, removed without contamination, should be injected into the brain of guineapigs and rabbits and the effects observed. This last test carried out by an experienced observer is the most trustworthy of all."—(MacNeal's *Pathogenic Microorganisms.*)

7. To demonstrate *gonococci:* On a cover glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismark brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes,* which have been *decolorized by Gram's stain,* and have taken the counterstain.

8. *Infection* is the invasion of the body by living pathogenic organisms under conditions suitable to the life and growth of the latter.

9. *Five culture media:* Agar, blood, milk, potato, and gelatin.

10. The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aerobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue.

A sterile swab is rubbed over any visible membrane on the tonsils or throat, and is then immediately passed over the surface of the serum in a culture tube. The tube of culture, thus inoculated, is placed in an incubator at 37° C. for about twelve hours, when it is ready for examination. A sterile platinum wire is inserted into the culture tube, and a number of colonies of a whitish color are removed by it and placed on a clean cover slip and smeared over its surface. The smear is allowed to dry, is passed two or three times through a flame to fix the bacteria, and is then covered for about five or six minutes with a Loeffler's methylene-blue solution. The cover slip is then rinsed in clean water, dried, and mounted. The bacilli of diphtheria appear as short, thick rods with rounded ends; irregular forms are characteristic of this bacillus, and the staining will appear pronounced in some parts of the bacilli and deficient in other parts.

### PATHOLOGY.

1. *Catarrhal* appendicitis is characterized by slight swelling and minute erosions of the mucosa. The muscular and serous coats will show slight infiltration and the lumen will contain epithelial and pus cells. In the *necrotic* or *gangrenous* variety the inflammatory processes are destructive. The mucosa is destroyed and the muscular and serous layers are soon attacked. The inflammation involves neighboring surfaces and a fibrinous peritonitis develops. This may be local, and by giving rise to adhesions between adjacent tissues no further extension takes place. The process may be very rapid and perforation follow before any restricting adhesions form; this is accompanied by a general and frequently fatal peritonitis. In *interstitial* appendicitis there is a tendency toward excessive connective-tissue formation and it generally terminates as a chronic thickening.—(McConnell's *Pathology.*)

2. There are two important forms of cirrhosis of the liver: hypertrophic and atrophic. The following table (from Thayer's *Pathology*) will assist in distinguishing them:

| | |
|---|---|
| *Synonyms.* Charcot's Hypertrophic, Unilobular Hepatogenous, Biliary. | Laennec's, Atrophic, Multilobular, Hematogenous, Hob-nail liver. |
| *Jaundice.* Early and marked, bile often absent from feces. | Late and slight, bile usually present. |
| *Ascites.* Late and unimportant. | May be early; often enormous. |
| *Spleen.* Enlarged early and markedly. | Late and less. |
| *Alimentary hemorrhage, piles.* Not common. | Common. |
| *Liver.* Large, smooth, mottled, green. | Small, rough, pale, or yellow. |
| *New fibrous tissue.* In fine lines and strands between acini and cells, involving all parts equally. | In broad bands, making prominent islands in which the single acinus may appear nearly normal; distributed irregularly. |

3. The following classification of the causes of stricture of the esophagus is taken from Herrick's "Medical Diagnosis": (1) *Intraesophageal:* Foreign body, mass of food. (2) *Interstitial:* Neoplasm; cicatricial tissue, as from toxic gastritis, ulcer (syphilitic, peptic); esophageal abscess; congenital; spastic stricture. (3) *Extraesophageal:* Enlarged glands, *e.g.* sternal, cervical, bronchial, from tuberculosis, cancer, suppurative adenitis; mediastinal, or cervical celulitis; vertebral disease; dislocation of hyoid bone or clavicle; cancer of pleura or lung; ossification of stylohyoid ligament; swelling of cricoid; pericardial effusion; cardiac hypertrophy; aneurysm.

4. *Progressive muscular atrophy.*—"Two theories as to the origin of the pathological changes are held: one that the initial lesion is in the cord (Charcot), the other, in the muscular interstitial connective tissue

(Friedreich). The morbid alterations are of two groups: spinal and muscular. The spinal changes consist in the atrophy and degeneration of the anterior columns, wasting and disappearance of the multipolar ganglion cells of the anterior horns with hyperplasia of the neuroglia; rarely, the hyperplasia extends to the lateral columns (amyotrophic lateral sclerosis; also atrophy, and degeneration of the anterior nerve-roots. The muscular changes consist of a progressive wasting of the muscular tissue, with increase of the interstitial connective tissue. The final result is that the muscle is converted into a more fibrous band with numerous fat cells, the development of this latter material taking place outside of the muscular elements and in the newly formed connective tissue."—(Hughes' *Practice of Medicine.*)

5. *Arteriosclerosis.* Causes are: Age, male sex, heredity, high living, alcohol, syphilis, uric acid, nephritis, tuberculosis, rheumatism, diabetes.

The large arteries are chiefly affected. The earliest changes are a small-celled infiltration of the subendothelial tissue, which may be either replaced by fibroid tissue or undergo fatty degeneration.

Degeneration usually occurs, and the softened mass either bursts into the artery or becomes converted into a calcareous plate. The process extends to the middle coat, which is at first softened, and the muscular tissue is destroyed in patches. The result is either weakening of the wall and dilatation into an aneurysm, or the deposit of lime salts and calcification of the middle coat. The external coat is thickened, and helps to prevent dilatation. The conditions which are secondary to atheroma are thrombosis, detachment of a plate forming an embolus, or "dissecting aneurysm," due to the blood-stream getting under a plate and tunneling under the tunica intima.

6. Gumma.

7. *Acute pleurisy* will give friction sounds, generally on one side only; *bronchitis* will give fremitus, and is generally bilateral.

8. A pure culture must be obtained. Liquefied gelatin must be inoculated with the mixture of bacteria, and after thorough agitation so as to separate each cell from its neighbor, the liquid is poured on to the surface of a sterile plate. The gelatin now solidifies and imprisons, as it were, the separated cells. Each of these now multiplies and reproduces its kind; eventually, in the course of a day or two, a small growth, perhaps of the size of a small pinhead, appears. This is called a colony, and since it is derived from a single cell it constitutes a pure culture. Such is the principle of the dilution method for obtaining pure cultures. The isolation once accomplished, all that is necessary is to transplant the colony to sterile culture media so as to keep up the growth.—(*Reference Handbook of the Medical Sciences.*)

9. The most characteristic lesion of typhoid fever is found in the lymphatic structures, especially in the solitary follicles, Peyer's patches, mesenteric glands, and spleen. In the first stage of typhoid fever Peyer's patches become swollen, hyperemic, and reddened; a few days later they appear as whitish or gray elevations, and the hyperemia has disappeared; the surface of the patch is smooth and its edge is sharply defined; after the first week necrosis may occur; the center of the patch becomes softer, more yellow, or sometimes even red from the absorption of blood pigment. The necrotic portion falls off, leaving an irregular ulcer, with necrotic and undermined edges. These ulcers are elongated, with the long axis parallel with that of the intestine, and a smooth floor. The ulcers may heal or go on to perforation.

The spleen becomes congested and enlarged, is liable to infarction, and contains the bacilli.

10. A *sequestrum* is a portion of dead bone which is separated from the living bone.

"This separation occurs by the process of demarcation, as in necrosis of the soft parts. This line consist of an area of absorption of the calcareous matter and proliferation of the cellular elements. The necrotic portion, or sequestrum, acts as a foreign body, and by its continued irritation keeps up a suppurative inflammation of the surrounding tissues. Fistulous communication with the exterior is usually observed. If the sequestrum is peripheral and has been discharged, the periosteum or the bone may replace the lost tissue by regeneration. If the fragment is large or centrally placed, discharge is impossible and suppurative inflammation continues, sometimes for years. In these cases considerable hyperplastic material may be deposited over and around the sequestrum, and thus irregular thickening of the bone may be produced."—(Stengel's *Pathology.*)

OBSTETRICS AND GYNECOLOGY.

1. By the *hygiene of pregnancy* is meant the care which should be observed by the pregnant woman for the preservation of health and strength both of herself and of the fetus. The pregnant woman should take moderate exercise in the open air; in the last month massage may take the place of exercise. Daily bathing in tepid water, care of the teeth, regularity of the bowels, ample sleep in a well-ventilated room, plenty (but not too much) of simple, nourishing and easily digested food, at regular hours, clothing not too tight, especially about the abdomen and breast; attention to the nipples, regular examination of the urine, and the restriction of marital relations are the main points to which advice should be directed.

2.—

| PREGNANCY. | OVARIAN TUMOR. |
|---|---|
| The usual signs of pregnancy are present. | There is an absence of the chief sign of pregnancy, as a general rule. |
| The patient is generally in good health, with an increase of body-weight; there is no characteristic facies. | In advanced cases the ovarian facies is present—a pale, drawn expression, with yellowness of the skin and general emaciation. |
| The abdominal tumor is hard, non-fluctuating, situated in the median line, and reveals the fetal signs. | The abdominal tumor is soft, fluctuating, showing usually more or less growth to one or the other side, and does not reveal the fetal signs. |
| There is generally a suppression of menstruation. | Continuance of menstruation is the rule, although it may be altered in character; suppression has been noted. |
| The cervix is soft (Goodell's sign). | The cervix is probably not altered. |
| There is history of exposure to the possibility of impregnation, with rapidly developing enlargement in the median line. | The history is obscure, with a slowly developing tumor beginning on one or the other side. |

—(Dorland's *Obstetrics.*

3. "*Puerperal eclampsia* is an acute morbid condition, occurring during pregnancy, labor, or the puerperal state, and is characterized by tonic and clonic convulsions, which affect first the voluntary and then the involuntary muscles; there is total loss of consciousness, which tends either to coma or to sleep, and the condition may terminate in recovery or death. The *causes* may be: Uremia, albuminuria, imperfect elimination of carbon dioxide by the lungs, medicinal poisons, septic infection; predisposing causes are renal disease and imperfect elimination by the skin, bowels, and kidneys.

*Symptoms:* Headache, nausea, and vomiting, epigastric pain, vertigo, ringing in the ears, flashes of light or darkness, double vision, blindness, deafness, mental disturbance, defective memory, somnolence; symptoms easily explained by the circulation of toxic blood through the nerve centers. These may be preceded by lassitude, and accompanied by constipation or by diarrhea. Headache is perhaps the most significant and common warning symptom. In bad cases the urine is reduced in quantity (almost suppressed), very dark in color, its albumin greatly increased, so that it becomes solid on boiling. Next comes the final catastrophe of convulsions. The convulsive fit begins with twitching of the facial muscles, rolling and fixation of the eyeballs, puckering of the lips, fixation of the jaws, protrusion of the tongue, etc., soon followed by violent spasms of the muscles of the trunk and limbs, including those of respiration; hence lividity of the face and stertorous breathing, biting of the tongue, opisthotonus, etc. The fit lasts fifteen or twenty seconds, ending in partial or complete coma, possibly death; or consciousness may return, to be followed by other convulsions."—(King.)

4. *Management of inevitable abortion:* "Two methods of treatment have been advised for these cases. The first is *the expectant plan:* Place the patient in bed,

and if the bleeding is profuse insert a tampon of iodoform gauze (one yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perincal pad and binder. Small doses ($5\frac{1}{2}$) of the fluidextract of ergot should now be given every two or three hours. At the end of from eight to twelve hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chloride (1:4000) must be given, and another tampon introduced. If, upon the removal of this second tampon at the end of ten or twelve hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted. *Active plan:* The physician's hands and instruments are sterilized; the patient is etherized and placed on an appropriate table; the genitalia are thoroughly cleansed and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps is introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly curetted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed. A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary, when the uterus refuses to contract and hemorrhage persists after the use of the curette."—(*Pocket Cyclopedia.*) The dangers are: Sepsis, hemorrhage, and subinvolution.

5. *Ligature of the cord.*—"As soon as respiration is well established, lay the child on the bed on its back. Wait for a few minutes until the cord shows signs of ceasing to pulsate. Then take the cord at a spot about two inches from the umbilicus, squeeze away the Wharton's jelly so as to make it a thin cord, and apply a ligature, and tie tightly with a surgical or reef knot. Apply a second ligature about three inches from the vulva. The second ligature is not necessary unless there is a second child in the uterus, when it may save its life if the circulations of the two children communicate. Cut the cord between the ligatures half an inch from the umbilical ligature. Take care to hold the cord up on the fingers when cutting, otherwise you may easily injure the infant. When the child has been bathed and is ready to be dressed, the cord should be carefully dried; it should be seen that it is not bleeding; then it may be powdered with boric acid and starch powder and wrapped in a small dressing of dry sterile gauze."—(From Johnstone's *Midwifery.*)

6. The *hand may be passed into the uterus:* To aid in version, to extract an adherent placenta, to remove a piece of placenta which has remained behind, to stop a postpartum hemorrhage. Except in the last case (when there is no time to be lost) the hand should be made as sterile as possible, and a sterile glove should also be worn.

7. The *dangers in the use of forceps* are: Sepsis, injuries to the soft parts or to the child, and hemorrhage. All antiseptic and aseptic precautions should be observed, extraction should not be made too rapidly, the utmost care must be employed, compression on the fetus (particularly on the skull) must not be too prolonged, the mother's bladder must be emptied, and traction should be exerted only during the pains.

8. *Care of mother during puerperium: "During the first week* the patient keeps the bed, but after the first few hours she has considerable license. She may assume the sitting or half-sitting posture to take her meals and to nurse the baby, and, if necessary, for evacuation of the bladder and rectum. She should assume the lateroprone posture both right and left, several times a day, and lie upon her abdomen for at least an hour daily. Frequent change of position favors uterine drainage and massages the uterine supports. *During the second week* she has greater liberty, while the greater part of her time is spent on the bed or lounge. She may sit up for her meals, to urinate, and for bowel movements, and she should spend at least half an hour, twice daily, in abdominal and leg exercises to keep up her muscular tone. *The third week* she may be moved to a chair for a part of the day, having the liberty of the room. After sitting up for any length of time she should be instructed to take the genupectoral position before lying down. Prescribed exercises for the legs and abdominal muscles are to be taken daily. *The fourth week,* if all goes well, she may leave the room and have the benefits of air and sun. Physical exercises should be continued. The duration of the lying-in period and the degree of freedom to be given the patient after the second week must, however, depend on the character and amount of the lochia, the general progress of her convalescence, and the rate of the uterine involution."—(Polak's *Obstetrics.*)

9. *Phlebitis* is inflammation of a vein, and is due to infection during labor or the puerperium. The most rigid asepsis and antisepsis must be observed by physician and nurse; and nothing which is not as near sterile as possible should be allowed to come in contact with the genital tract of the parturient or puerperal woman.

10. *Mammary abscess* is characterized by pain, swelling, tenderness, feverishness. Sometimes it begins with a chill, fluctuation may be elicited, the neighboring lymphatic glands may enlarge. *Treatment* consists in making an incision radiating from the nipple, and drainage, though antiseptic and aseptic precautions must be observed; the breast should be put at rest for a couple of days; saline cathartics may be necessary, also supportive measures.

(*To be concluded.*)

## BULLETIN OF APPROACHING EXAMINATIONS

| STATE | NAME AND ADDRESS OF SECRETARY | PLACE AND DATE OF NEXT EXAMINATION† |
|---|---|---|
| Alabama* | W. H. Sanders, Montgomery | Montgomery |
| Arizona* | J. W. Thomas, Phoenix | Phoenix |
| Arkansas | W. S. Stewart, Pine Bluff | Little Rock....May 12 |
| California | C. B. Pinkham, Sacramento | Los Angeles ...June 16 |

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Oklahoma now reciprocates with the following States: Texas, New Mexico, Nebraska, Nevada, Michigan, Wisconsin, Indiana, Kentucky, Arkansas, Tennessee, Mississippi, Georgia, North Carolina, West Virginia, and New Jersey.

**The Backflow of Pancreatic Juice into the Nursling's Stomach.**—A. Reiche concludes from his observations that there is a distinction between the young infant and the adult in regard to the backflow of pancreatic juice into the stomach. Whereas, in the adult this phenomenon has been frequently observed, in the nursling it has not yet been demonstrated. The digestion in the nursling's stomach of fat and albumin by means of the ferments of the pancreatic juice may therefore be excluded.—*Zeitschrift für Kinderheilkunde.*

### THE NUTRITIVE SIGNIFICANCE OF DIFFERENT KINDS OF FOODSTUFFS.*

By LAFAYETTE B. MENDEL, PH.D.,

NEW HAVEN, CONN.

PROFESSOR OF PHYSIOLOGICAL CHEMISTRY, SHEFFIELD SCIENTIFIC SCHOOL OF YALE UNIVERSITY.

Among the modern sciences that bear upon the everyday life of man there are few which appear to meet with so little popular recognition as does the science of nutrition. The average individual, among laymen and physicians alike, regards the fundamental problems of food and diet as permanently solved. He worships the dictates of custom and habit in matters pertaining to his nutritive welfare, satisfied to depend upon the long experience of the past. A person who has promptly accepted the latest and most radical pronouncement of modern hygiene and adjusted his living conditions to meet the newest suggestions in the domain of sanitary science, is as likely as not to ridicule even the conservative conclusions of a student of dietetics.

Few of us realize that despite the apparent permanence of our dietary habits, these really represent the results of a progressive change in methods. Man did not always prepare his food by the procedures which are now-a-days regarded as fixed and unchangeable. Until the art of cooking was perfected the régime of the human individual must have been different from much that is now almost universal. Primitive methods were inevitably unlike the present day practices. "Water could not be a cooking medium until man advanced at least to the first stage of pottery making, when some rude basket daubed with clay was water-tight and sufficiently heat-proof." (Kinne and Cooley.) Indeed, one may well ask why we cook at all. "Primitive man thought only that the food had a better taste. He may have decided, too, that it was easier to masticate; but we have learned that in some cases we may, with right methods of cooking, make it easier to digest farther on in the alimentary canal. Modern science carries us a step farther and teaches us that cooking destroys lower organisms, such as harmful bacteria that may be present, and even animal parasites in meats." (Kinne and Cooley.)

Again, peoples in widely separated parts of the earth subsist upon the greatest diversity of unlike foods. The meat and blubber of the Eskimo contrast with the rice and vegetables of the Filipino in source and numerous details of composition; yet no one would venture to maintain that either dietary is utterly inadequate. In the face of such reminders of the inequalities of food supply set by geographical or economic conditions, and of the variations progressively evolved in the historic development of races, we need no longer approach the question of possible reforms in dietetics in an apologetic way. On the contrary, he would be rash indeed, who were bold enough to assert that the final word in relation to practical nutrition has been spoken.

Food constitutes the chief item of the living expenses of the people; yet most of them understand very little about what it contains, what are its functions as nourishment, whether they are economical or wasteful in their purchases and the preparation of the diet, and whether they are satisfying their nutritive needs in adequate measure. The reason for such ignorance a generation or two ago is easily appreciated. The first analyses, by modern methods, of materials for the food of man or domestic animals were not made in this country until 1869. Little was known about the composition of the body, of the nature of the nutritive ingredients, and the amounts of them required. Since then progress has been rapid. The statistics of nutrition have been accumulated abundantly and widely.

Probably no single contribution to the science of nutrition has been more fruitful in its consequences than the calorie idea. It was no small achievement to put the body's need for physiological fuel upon a definite basis and to give a concrete significance to the energy factor in nutrition. The food requirement has at length become a matter of accurate estimation rather than intuition. Undernutrition can be demonstrated by direct dietary investigations. The increased demands for food fuel for the working man, as well as the relative abundance of the ration of the infant at different stages of growth, need no longer remain veiled in the mystery of guesswork.

Only within the past twenty years has the development of scientific methods rendered possible really accurate investigations relating to these questions. As Professor Armsby has lately expressed it: "They show that the transformations of chemical energy into heat and work in the animal body take place according to the same general laws and with the same equivalencies as in our artificial motors and in lifeless matter generally. The great law of the conservation of energy rules in the animal mechanism, whether in man, carnivora or herbivora, just as in the engine. The body neither manufactures nor destroys energy. All that it gives out it gets from its food and all that is supplied in its food is sooner or later recovered in some form. We are fully justified, therefore, in speaking of the food as body fuel, and in our studies of its utilization we may be confident that any food energy which does not reappear in the

*Read at a meeting of the New York Academy of Medicine, March 19, 1914.

form of heat or work has not been lost but has been stored up in the body as the chemical energy of meat, fat, etc., which may later serve to supply food energy to the human body."

There are, however, certain limitations in the application of the calorie idea in nutrition that are sometimes overlooked. It is not sufficient that a food material should give evidence of energy-yielding components in the laboratory of the food chemist. The energy must be available. Filter paper and cotton wool, finger nails and hair, paraffin and wax, are instances of carbohydrate, protein, and fat-like products; but inasmuch as they cannot be digested and absorbed by man the calories which they yield in the laboratory can never be put at the service of the organism. Physiological analysis must supplement the conventional tests of the chemist whenever innovations in articles of diet are proposed.

The foregoing remarks serve further to direct attention to another step in the path of progress—the recognition of the dominant importance of digestion in nutrition. The familiar proximate principles in the foods—the fats, carbohydrates, and proteins—are not the immediate nutrients of the tissues. The functions of tissue construction and metabolism are relegated entirely to the products of the profound digestive changes to which the food is subjected in the alimentary tract. It is amino-acids and simple sugars like glucose, not albumin and starch, nor albumose and dextrin, nor even so simple a compound as cane sugar, that furnish the immediate pabulum for the hungry cells. It would be interesting, if time permitted, to dwell upon what this newer knowledge means in the practical work of the physician. To furnish undigested food where the alimentary processes are an impossibility, is a useless waste and may be a positive menace.

The modern conception of dietary deficiencies, rudimentary as it still is, nevertheless differs fundamentally from the food superstitions of a century ago. The development of the idea that the ration of man can be defective in both quantity and quality has served to place many disease conditions in a new light. Invading microorganisms and pathological neoplasms are no longer to be regarded as the sole forms of menace to the body. A pronounced lack of iron or of calcium may also bring nutritive disaster in the long run.

Deficiencies of this sort are not as common as those of protein and energy. Instead of providing for them from the drug store, however, we are learning to supply iron by using larger quantities of eggs, green vegetables, fruits, and the coarser milling products of the cereal grains; and to correct a shortage in calcium by using larger amounts of milk and cheese. Indigestible food material, as it occurs in so many plant products in the form of cellulose and related carbohydrates, is properly looked upon as "roughage"—an adjuvant furnishing to the diet a frequently desired texture or bulk.

Among the novelties of viewpoint in the domain of food deficiencies is the appreciation of the chemical dissimilarities between different proteins. They vary among themselves in respect to the proportions of the amino-acids which they can yield. Some, like gelatin or like zein, the chief protein of the maize kernel, are even completely lacking in certain of these nutritive units. The possible physiological significance of this appears in a new light, now that the apparent inability of the animal body to construct some of the amino-acids is known. There are amino-acids, like tryptophane, which are doubtless indispensable to life; others, like lysine, which are essential for new tissue construction such as occurs in growth; others again, like glycocoll, which the body itself can manufacture as needed. The physiologically balanced ration of the future, therefore, will not merely take into account the energy value and relative proportions of the great groups of familiar nutrients. It must realize the need of a suitable supply of more specific products. The widely debated question of high- and low-protein derives a new significance when the dissimilarity of the individual proteins and their unlike nutritive rôle is taken into account. It is futile to speak of a protein minimum; for there are various minima set by the chemical unlikeness of the nitrogenous components of the diet.

Recent researches have revealed the possible existence of even more subtle factors than the energy-yielding fuel or the tissue-constructing components of the diet. Thus supposed growth-promoting constituents, minute admixtures of substances which avert special forms of malnutrition such as are seen in scurvy and beriberi, and similar, as yet vague, food accessories are being presented for recognition. The appreciation of the possibilities in this field has only begun, and the overhasty generalizations already heralded are to be condemned. One need, however, only recall the remarkable Wisconsin experiments showing the widely unlike outcome of the prolonged feeding of cattle on so-called balanced rations, derived in each group entirely from a single plant source, to learn the importance of the newer knowledge. Fortunately the diet of most classes in our American communities is so varied that the chance of continually missing essential adjuncts is small. For this reason every innovation pertaining to the nutrition of the masses should favor a comprehensive rather than a restricted source of the nutrients. No fad or doctrine which limits the range of food supply should be tolerated so long as our information is still so limited. Too often it is prejudice or propaganda, rather than poverty, which enforces unsuspected deficiencies.

A few instances of widespread misconceptions and bias in respect to foods may serve to emphasize some of the points already alluded to. An unjustified prejudice against certain so-called "artificial" foods is still retained in the minds of many. This applies especially to commercial glucose. It is not easy to understand why the hydrolysis of starch in a factory needs to be condoned, when one recalls the similar service which is daily rendered by the alimentary tract of man. Unfortunately the misguided policy of a few manufacturers, whose unscrupulousness now appears more as an exhibition of stupidity than of crime, has served to divert attention from the fundamental teaching of science in respect to glucose. Quoting an authoritative government bulletin: "Its nutritive value is practically the same as that of other carbohydrates, and there is no reason to suppose that when properly made it is not wholesome." (Abel.) Obviously the extensive use of isolated foodstuffs like glucose, in the dietary, might well lead to a nutritive impoverishment in the important accessories that occur in the natural foods. That is, however, another matter and applies equally well to commercial cane sugar which is, in a sense, likewise an

"artificial" product sanctioned by the custom of comparatively few years. Aside from the peculiar appeal which cane sugar makes to the palate there is at present nothing to recommend its superiority over the other related sugars that find their way into the diet. I might cite the most vigorous condemnations of cane sugar and beet sugar respectively in current publications—all based upon a fabric of pseudoscience or ignorance.

The debate of red *vs.* white meats is resumed at less frequent intervals than formerly and would scarcely deserve mention here were not physicians the chief offenders in reviving it. Unfounded discriminations and prescriptions of this sort sometimes involve unnecessary expense to those who can least afford it.

In the undervalued and maligned banana we have an example of what ignorance and improper habits of eating can do to detract from the deserved popularity of a wholesome food. Bruised, damaged, and exposed to decay by improper methods of marketing and serving, though nature furnishes the banana in a sterile package; eaten before it is ripe because the green fruit appears more attractive to some; insufficiently masticated by many, though rarely by untutored children; this delicious fruit has acquired an unmerited reputation as an indigestible offender. The real culprit is man, not the banana; and why he should disdain a raw potato or a green apple, yet attempt the alimentary conquest of an unripened, indigestible starchy banana instead of the duly ripened sugary fruit—and then expect comfort—is a mystery.

Owing to an inexplicable tradition of unknown origin it is still necessary in America to issue a physiological defence of cheese. Although it has been employed in the most diverse parts of the world for untold years as a staple of diet, there are not a few people who continue to regard this relatively cheap, wholesome, and palatable food product as likely to produce alimentary disturbances. It is high time for this delusive assumption to be dismissed from the public mind. The myth of the indigestible cheese belongs in the same category with indigestible beefsteak or indigestible milk or indigestible pie—all coming within the range of human possibility, but chargeable primarily to culinary or personal shortcomings rather than to any dietetic imperfection of the food itself. Condimental cheeses of high flavor and peculiar texture may best accompany a moderate menu and thereby add to its attractiveness, but the mild-flavored sorts can well serve as substantial components of the dietary to replace other protein foods, particularly where expense is an item of inevitable importance.

The prejudice against skimmed milk has a different origin. It owes its inception to the undisputed fact that the removal of the cream decreases the nutritive value of milk, and if done surreptitiously constitutes an adulteration and a fraud. The residual milk is, however, in no way damaged by the lack of fat. It is a wholesome source of protein, sugar, and other dietary essentials which should not be despised because they are present in a discarded by-product of cream and butter manufacture which sometimes is misrepresented to be whole milk. The widespread aversion to the purchase of cream-free milk is undoubtedly in part due to the confusion of the criminal motives of an occasional dairyman with the residual nutrient possibilities of the food product.

Among other familiar dietary traditions is found the idea that all acid fruits, or strictly speaking, the organic fruit acids, function as true acids in the organism. Most of them, like citric and malic acids, to which may be added the widely used lactic and acetic acids, are burned up in metabolism, so that their salts behave like potent alkalies. Sodium citrate is equivalent in this sense to the carbonate of the alkali. Tartaric and benzoic acids form exceptions to the rule and traverse the body unchanged. The grape and plum, the prune and the cranberry, with their non-metabolizable acids, thus differ from the apple, orange and lemon, from vinegar and sour milk, in respect to the behavior of their acid component.

It is not only in the direction of antipathy that dietary notions are often perverted. Certain foods, like the mushrooms, have been the subject of overenthusiasm. We read about the neglected wealth of delicious vegetable beefsteak of the fields left to decay when it might fill the nutritive wants of the underfed multitudes, if only they were encouraged to gather the fungi. The error of the belief was pointed out by me long ago. The edible mushrooms are anything but rich in the longed-for protein; indeed, they scarcely approach the crudest vegetable in food value. The chemist, like the mushroom lover, has in the past been misled into false conceptions regarding the virtues of these vegetative forms.

Final pronouncements are not always reliable in the domain of nutrition. Viewpoints may change. A few years ago we learned to reject the claims of the extraordinary virtues of the extract of meat as a real nutrient. To-day, while admitting the justice of this attitude, the newly recognized unique influence of the same product in provoking the flow of the digestive juices places a new interpretation on the dietary rôle of soups and bouillon, and opens a new field for their application in dietotherapy. The new researches in anaphylaxis have likewise taught the need of conservatism in judging alleged idiosyncrasies to food. Strawberries, buckwheat, eggs, milk, shellfish—all may offend the hypersensitive individual in ways that promise soon to be explained along rational lines. Well authenticated claims need to be recognized and interpreted in some more modern spirit than that which expresses itself in the indefinite misnomers of autointoxication or ptomaine poisoning.

The time has come for the unravelling of fact and fancy in practical dietetics. It is not unlikely that some of the apparently inexplicable, yet empirically demonstrated results of special forms of feeding may become untangled as the newer ideas are introduced into the analysis of problems of nutrition. The studies of Osborne and myself and others on growth lend some sanction to the popularly accepted superior value of cod-liver oil, of egg yolk fat, and butter in contrast with other more familiar food fats. There are demonstrable physiological virtues in milk which cannot be expressed in terms of energy or the familiar nutrients. In breaking away from stolid empiricism and conservative indifference in matters of diet, we need not be blind to the valuable contributions embodied in the experience of generations of mankind. But when the physiologist has succeeded in some degree in interpreting or correcting this experience, it will become the duty of the dietitian and of the physician to act as advance agents in the promulgation and the application of the newer knowledge in everyday life.

# FOOD FROM THE STANDPOINT OF ENERGY.*

By GRAHAM LUSK,

NEW YORK.

THE popular agitation of the pure food question has caused the mind of the public to respond to certain chords of enthusiasm when struck by certain leaders of the movement and yet there is much of underlying truth which has entirely escaped the serious minded individual. This is due to the fact that there has been necessarily involved in the movement much that is in the nature of commercial warfare. Take, for example, the manufacture of tomato catsup. One manufacturer heralds his product as a pure food product because it is free from benzoate of soda. The public is delighted and trustfully purchases the product. It has no knowledge that the quantity of benzoate in the rival product is so small as to be entirely harmless, or that the catsup which is free from benzoate may have been prepared from decayed tomatoes whose inferiority is entirely disguised by the oil of cloves and other spices which have been added to the preparation.

This shows that, above all, pure food calls for honest inspection at the sources of its production and distribution. It means cleanliness. And this begins in the individual home, in the icebox of the citizen and next in the icebox of his butcher. Sometimes one wonders of what value pure food can be to the poor when they are permitted to use the streets in which their children play as places for the dumping of refuse.

Another imperfectly understood problem is the quantity of food needed for the support of a man. This ignorance causes much misunderstanding and is all the more astonishing since successful cattle raisers have long since applied the principles of scientific nutrition for the well being of their cattle and with wonderful success. Why not the same for babies and for families? The educated physician can intelligently prescribe proper diets for the sick. Why cannot scientific knowledge be made effective in welfare work among the general populace? Instead of the distribution of real knowledge one can recall the political war-cry of a "full dinner pail" and the socialists' dogma that half the world is starving. A newspaper has published articles on "Starving America," in words calculated to make the judicious grieve and the hair of the nervous to stand on end. If there were any truth in the allegation that America is "starving" it would be indicated in the vital statistics, and the citizen of New York City would not be able to point to the fact that the death rate was lower in 1913 than in any of the great cities of the world.

If the statements which have been made in these opening remarks appear to be sensational and contrary to the doctrines expounded by one's favorite newspaper, it should be recalled that the truth is often sensational. It has been stated that if at the beginning of the month a person made up his mind to tell the truth freely on all subjects, he would find himself in jail before the month was over.

Even an educated person accomplishing his usual tasks and enjoying the pleasures of life may never have thought that all his activities were dependent on the oxidation of the food stuffs which are in his breakfast, dinner, and supper. A word with him about his "heat production" reveals the fact that he is not aware that he is producing any heat—except when he is angry. His life is so full of interesting events and pleasant reflections that it has never occurred to him that the dead body is cold because the oxidative processes are no longer active, and that his body is warm because of the continued burning of materials within himself. This maintains him as a machine. When he has taken vigorous exercise to which he is unaccustomed, he rejoices that he has a fine appetite, but he does not consider that the larger intake of food is merely to replenish the body on account of the increased fuel consumed by the body's muscles in order to accomplish the work done.

The demand of the body for fuel in the form of food is inexorable. If it is not supplied death from starvation occurs. In the case of infants it takes days in the case of adults weeks to bring about the fatal result.

How necessary a knowledge of nutrition may be follows from this typical story. The father was a woodsman of the mountains, and the local physician deficient in a knowledge of nutrition. The baby was sick, retained no milk when given it, and had been placed on a diet of oatmeal water with a little milk sugar. The baby cried all night, the mother was worn out, and the physician reported the case as one of chronic malnutrition. The remedy was easy. Diluted whey and milk sugar led up to diluted milk and milk sugar, calculated to contain a sufficient supply of energy. The baby slept and throve. The alleged state of "chronic malnutrition" was nothing but one of partial starvation.

The body of the infant must be supplied with food to promote growth and to maintain the motions of life whose sum total are measured by the heat produced. In the adult a quantity of food fuel is necessary to maintain the body in repair and to yield the energy which affords the power to accomplish mechanical work.

Dr. Mendel has spoken about the limitations of the caloric method of computing nutritive values. And yet, all in all, it is the best method. Nature, through the device of appetite, usually provides against the use of wrong food. A man who leads a life of sedentary occupation requires 2,500 heat units or calories to maintain his body machinery. He needs also water, salts, proteins, and certain newly discovered substances called vitamines. All these materials are to be found in milk, beans, bread, and other great fundamentals of nutrition. He will not take solutions of cane sugar or of glucose as the exclusive mainstay of his life. Yet glucose taken alone yields 2,500 calories at a cost of 4 1/6 cents, and 2,500 calories in the form of cane sugar costs 8 1/3 cents. Glucose is the cheapest food fuel known, but, like cane sugar or butter fat, is not a complete food, in that it does not contain everything necessary for life. Commercial glucose is absolutely harmless. The author has taken 4 ounces in water, a friend has taken 8 ounces. Of course, this does not mean that because one can take into the system 750 calories contained in glucose and oxidize it, that glucose alone can exclusively be used, in the way that gasoline can be used in the engine. Human fuel is always a mixture of food substances and mixed so that the taste is agreeable. Glucose has been frequently administered in typhoid fever and children of the author's friends have taken it without the slightest harmful result. Pancakes eaten with a syrup in

*Read at a meeting of the New York Academy of Medicine, March 19, 1914.

which glucose forms the basis of composition gives a cheap and nutritious form of food strengthening and appetizing to young and old alike.

This merely presents the idea of how food may be regarded as fuel.

It has already been remarked that the person who leads a life involving sedentary pursuits requires 2,500 calories for his maintenance. Recent work of Becker and Hämäläinen in Finland has shown how much energy is needed by people in various occupations. The women may be first considered. The work day was of eight hours.

A seamstress sewing with a needle required 1,800 calories.

Two seamstresses using a sewing machine required 1,900 and 2,100 calories, respectively.

Two bookbinders required 1,900 and 2,100 calories.

Two household servants employed in such occupations as cleaning windows and floors, polishing knives, forks and spoons, polishing copper and iron pots, required 2,300 to 2,900 calories.

Two washerwomen, the same servants as the last named, required 2,600 and 3,400 calories in the fulfilment of their daily work.

Concerning the fuel requirement for the occupations of men:

Two tailors required 2,400 to 2,500 calories.

A bookbinder required 2,700 and a shoemaker 2,800.

Two metal workers, filing and hammering metals, required 3,100 and 3,200 calories.

Two painters, occupied in painting furniture, required 3,200 and 3,300 calories, and two carpenters engaged in making tables required the same amount of energy.

Two stonemasons chiseling a tombstone needed 4,300 and 4,700 calories.

Two men sawing wood required 5,000 and 5,400 calories.

The proverbial reputation of sawing wood as a strenuous occupation has here its scientific verification and explains the disinclination of the hungry to engage in this useful occupation, as well as the unpopularity of charitable wood yards.

The above-mentioned series of experiments were made upon men and women the intensity of whose oxidation processes was determined by the direct measurement of the carbonic acid gas which they expired. The calories required were calculated from this. It was further found that this calculated requirement of energy was approximately the quantity which the individuals were actually taking in their food.

The figures are highly significant. A man must have sufficient calories in his diet if he is to live properly and perform labor satisfactorily.

| | Cost in Cents per 1,000 Calories | Per Cent. of Calories in Protein |
|---|---|---|
| Glucose | 1 2-3 | 0 |
| Corn meal | 2 | 8 |
| Wheat flour | 2 1-2 | 12 |
| Oatmeal | 2 4-5 | 13 |
| Cane sugar | 3 1-3 | 0 |
| Dried beans | 4 | 19 |
| Salt pork (fat) | 4 1-2 | 1 |
| Rice | 5 | 7 |
| Wheat bread | 5 1-3 | 12 |
| Oleomargarine | 7 1-2 | 0 |
| Potatoes | 7 1-2 | 8 |
| Butter | 10 | 0 |
| Milk | 10 | 17 |
| Smoked ham | 10 3-4 | 34 |
| Cheese | 11 2-3 | 25 |
| Loin pork | 12 1-4 | 18 |
| Leg of mutton | 16 1-4 | 30 |
| Sirloin beef | 21 | 37 |
| Turkey | 40 1-4 | 37 |

One may reach an approximate monetary valuation of energy from the preceding table which shows the cost of 1,000 calories in various fundamental foodstuffs. In a second column the percentage of protein calories has been added.

These are foods at Washington Market prices. If the cost of cooking and serving and rental be included, the cost increases. Thus at Child's restaurant pork and beans served with three slices of bread and a piece of butter costs 18 cents per thousand calories. This restaurant caters for a well-to-do portion of the public.

It would be a matter of great interest if some benevolent person would establish a restaurant which prepared pork and beans on a large scale and sold it hot with bread and with a large cup of hot coffee which was made half with milk. Possibly in this way 1,000 calories in a well-balanced ration could be sold for about 10 cents, and most people after leaving such a repast would feel very comfortably satisfied. It would be most economical to serve only this one satisfactory ménu. If the patron of such a restaurant acquired larger means he could buy beefsteak at his pleasure elsewhere, but he could always feel that something substantial and of benefit to his body could be had for 10 cents (or less) if he wished it. It would be a fine alternative to the free lunch offered in the saloon. It seems as though the sale of a standard balanced ration at little or no actual profit is a very reasonable way to help the hungry and strengthen those who do not understand the right way in which to obtain real nourishment for the support of their work.

Of course, it is understood that this diet will not satisfy everybody. It especially will not satisfy those of all classes who demand the luxuries of the world without rendering to the world an equivalent therefor.

The writer has elsewhere ("The Fundamental Basis of Nutrition": Yale University Press, 1914) set forth his view regarding the desirability of placing on the label of every package, can, glass, or jar containing food, a statement as follows: "This contains x thousand calories, of which y per cent. are proteins of grade A, B, C, or D." The adoption of such a plan would, at a glance, inform the prospective purchaser the approximate nutritive value of the article examined.

There has been space to follow out only a certain line of thought, but the whole question of economical nutrition is well worthy of serious consideration. It should be taught to girls in the schools that in their own homes benefits may be reaped. The science of nutrition offers to social workers much that could be of value to the community if it were well enough understood to be practically applied.

## RESULTS OF THREE YEARS' CLINICAL WORK WITH A NEW ANTISERUM FOR CANCER.*

By WILLIAM N. BERKELEY, A.B., M.D.,

NEW YORK.

THIS paper is a clinical summary of my experimental work of the last three years upon the preparation of an antiserum for cancer. The first two of the three years' work was partly done at the Loomis Laboratory of Cornell University, with the very helpful scientific advice and sympathy of the director, Prof. S. P. Beebe, to whom my hearty

*Read before the Section of Obstetrics and Gynecology of the New York Academy of Medicine, March 24, 1914.

thanks are herewith extended, as well as to the trustees of the Huntington Cancer Research Fund for valuable financial aid.

The work here described has been in direct continuance of that provisionally reported before this same Section in February, 1912—two years ago—by Dr. Beebe and myself.

But little introduction is required. I may, however, observe once more, as was remarked in the former paper, that local remedies for cancer, such as fulguration, radium, and *x*-rays, can rarely meet the indications in full, because typical cancers metastasize, and the secondary growths develop in distant vital organs where local treatment is impossible. Therefore a scientific remedy for cancer must be one which is soluble in the blood and lymph, capable of transportation, thereby, to all portions of the organism, and possessed of a selective affinity for the cells of the tumor to be destroyed.

In view of the numerous and successful modern immunity studies of the bacterial cell (tetanus, diphtheria, and others) it is but a step to conceive of the plan of attacking the cancer cell in the same way. The idea was advanced years ago by v. Dungern and a voluminous bibliography was published on the subject by E. Vidal in 1911 (Transactions of the International Cancer Congress, Paris, same year), with some suggestive experiments by the author along the same line. Beebe's success with a thyroid antiserum in 1906 gave a further stimulus to the cytotoxin idea in this country; and there is little doubt that the human ascitic fluid so successfully used by Eugene Hodenpyl during the two years before his untimely death in 1910 was of the same general character.

Perhaps the measure of success that has attended my own work, where so many others have failed, has come largely from careful attention to small details in the chemistry of the cancer antigens used, and to patience in studying the effects of injections in various parts of the body of the experimental animal, dosage, interval between doses and species of animal used. All these points, however, will be considered at a more convenient season. This paper is a report of clinical results only, and is addressed exclusively to practising surgeons.

For a surgical cure of cancer four or five years are usually demanded; hence, my present results are provisional only. But they are, I think, worthy of comment.

To gain a sufficient and convincing clinical experience I have used my serum upon patients with many kinds of malignant tumors, and in all clinical and pathological stages. Out of 104 cases seen in the period mentioned only 15 were turned away as being too far advanced to give reasonable hope of at least temporary relief.

In the same period I have received between 135 and 140 tumors sent me from time to time by surgical friends interested in the research. Of these growths about 25 per cent. proved to be nonmalignant or atypical; the rest were used in making stock and autoserum.

Of all the malignant growths removed by primary operation microscopic sections are now in my possession except in three instances—where the clinical evidence was overwhelming, or where some other pathologist was intrusted with the diagnosis. In the cases of recurrent and inoperable cancer that have been treated also, I have sections of nearly all the growths. All these sections are now on file.

The clinical diagnosis was made in nearly every case by from two to a dozen surgeons, some of them among the most eminent in this country, and errors in the cases diagnosed malignant I believe to be negligible.

The Serum.—Taking first the serum, it has been given in doses of 5 to 50 c.c., intravenously and subcutaneously at intervals of a few days. It has been used in most cases unmodified except by inactivation. Latterly I have gotten much more satisfactory results with a serum concentrated by the method of E. J. Banzhaf, of the New York Department of Health. And here I must not neglect to acknowledge gratefully Dr. Banzhaf's personal and kindly assistance in this part of the work.

The *anaphylactic effects* (blushing, swelling, urticaria, pain, and rise of body temperature) with the unmodified serum have continued to be about as formerly reported. Out of several hundred injections there have been two cases (not in my care) of immediate and alarming anaphylactic shock following intravenous administration, from which, however, the patients made a prompt and satisfactory recovery after stimulation. Such accidents can, I believe, be largely avoided in susceptible patients by suitable precautions, and by using concentrated serum, which is much less toxic. On the other hand, some patients have repeatedly taken 30 c.c. of rabbit serum and 50 c.c. of sheep serum intravenously without the slightest local or general reaction, and one patient looked forward with pleasure to her (subcutaneous) injection and always felt better within half an hour after.

*Therapeutic Effects.*—In the matter of laboratory tests of the efficiency and strength of the various sera sent out, progress of the highest importance has been made. Precipitin reactions I have given up. They may be made readily to occur with fresh suspensions of cancer cells (sterilized with chloroform, not over four days old), but, while specific to a certain extent, the quantitative relations *in vitro* are vague, and the clinical results variable. Latterly I have found that a complement fixation test is quite practicable. and not only practicable but so delicate that the amount of antibody in each serum may be accurately titrated. I should, perhaps, make this claim with some reserve, inasmuch as many professional serologists say it has never been done before by any one who knew how, and a few even declare that it cannot be done. However, this is a part of the subject that will require careful treatment elsewhere.

After early primary operations we are able, of course, to judge of "cure" only by the failure to recur in a given time, but in treating secondary or inoperable growths one may reasonably rely upon the following criteria: (1) Relief of pain, (2) gain in weight, (3) shrinkage of the tumor.

The serum is best given in ascending doses intravenously. When this method is badly borne intramuscular injections will be found to work almost as well. As in the case of all therapeutic sera, immunity develops (anti-antitoxin) generally after six or eight injections. Though there have been some happy exceptions to this rule, the indications are that a cancer which cannot be cured by six or eight maximum injections will not be amenable to the serum treatment.

Clinically this confines the serum treatment to: (1) The destruction of microscopic remnants left after a primary operation; (2) the production of

immunity to cancer in persons not yet clinically ill of the disease but threatened with it; *e.g.* cases of *leucoplakia linguæ*, old ulcer of the stomach, bad cervical tears, chronic uterine inflammation, persistent mastitis. Such an application as this may not unlikely prove to be its sphere of greatest usefulness as soon as it can be prepared in larger quantities and at less expense. But the demonstration of its prophylactic value in these cases will, of course, be generally denied till its curative effect has been set upon a permanent basis; (3) a very few early and localized recurrences will probably be curable.

CASES.—Eighty-nine cases were regularly undertaken. Several changed their minds after operation and refused the serum. Several died of the immediate surgical procedure. In my early ignorance of the proper dosage and fear of dangerous by-effects I gave my first two cases six and eight doses respectively of one-half of one cubic centimeter. Both recurred in six weeks. Three cases received one dose (5 c.c.) only, and cannot be counted. This leaves 71 cases—32 secondary or inoperable and 39 treated after primary operation.

None of the cases classed as inoperable has been cured, but from the point of view of the research the results are of prime importance. Over two-thirds of them made a favorable response for a time; only six or eight entirely failed. Out of the 25 that were benefited I may call attention to the following, selected almost at random:

Case 20 in my files, maiden lady of 43 years, had a foul, ulcerated recurrent breast tumor 3 inches in diameter. The ulcer healed in six weeks, and in two months nothing was left of the growth except a nodule of the size of a hickory nut. The patient then unfortunately refused further treatment. I have written to her physician, Dr. Samuel Pierson, of Stamford, Conn., for recent news of her. No reply. Microscopic sections from this case were examined by four of the best pathologists in the city. All called it typical cancer.

No. 3 had a huge infiltrating cancer of the left lower jaw starting in the mucous membrane of the mouth near the tonsil. Pain entirely relieved for six weeks, and tumor reduced to half its size.

No. 7, an aged laborer, had a slowly growing cancer of the esophagus and had swallowed no solid food for nearly two years. After three injections his pain was entirely relieved, and he ate meat, bread, and vegetables for several weeks. The effect of the serum then wore off and the patient relapsed.

No. 16, fungating cancer of the tonsil, Irish laborer, 55 years, was relieved of his pain for six weeks, and part of his tumor sloughed, the rest shrinking somewhat, then slowly beginning to grow again.

No. 25, in care of Dr. L. G. Baldwin, had a recurrent uterine cancer in the bladder and vaginal *cul-de-sac*. Bladder symptoms disappeared for several weeks, and the vaginal nodule was reduced to half its size. All the symptoms then recurred without further response (cervix serum).

No. 27, recurrent breast cancer, supraclavicular nodules softened and shrunk, and pain relieved for two weeks; then relapsed (breast serum).

No. 19, unmarried woman of 40 years, breast case. Recurrent cutaneous nodules and enlarged axillary glands shrunk up markedly, some disappearing. Pain relieved entirely and morphine discontinued up to the time of her death, which was caused by influenza 6 months after treatment was begun.

No. 2, boilermaker, 46 years, referred by Dr. B. P. Riley. Massive cancer of the tongue; whole organ was involved and had attained the size of a bullock's tongue, protruding from the mouth; agonizing pain, cachexia, enlarged submaxillary glands, enlarged spleen. Pain relieved for three weeks, general shrinkage of the growth; spleen at the end of two weeks hardly palpable. Symptoms then recurred, and the patient ceased to respond to the injections.

The following report of No. 22, which I did not see, has been kindly sent me by Dr. John Van Doren Young, her physician, (original letter on file): "The patient, Miss V., 38 years old, came to me January 30, 1912. She had a large carcinoma of the right breast which had ulcerated, and the axillary glands were also involved. The left breast was also a mass of carcinoma; glands not so large and no ulceration (diagnosis confirmed by microscope). Operation February 2, 1912; both breasts, all muscles and glands removed—a most severe and as complete an operation as possible. March 13 I removed nineteen small recurrences. Within a few days several more were seen and I asked Dr. W. M. Ford to see her in consultation. When he examined her there were thirty-five nodules. After the first injection of serum sent by Dr. Berkeley no more made their appearance, and those that were present turned blue in the course of the next five injections, then dimpled, turned blackish, dried, and could be picked off. * * * I do not know how to interpret the effect in this case, but it was most remarkable."

This patient was a Spanish lady, only temporarily in New York and without means, and when Dr. Young refused to guarantee her a cure from further treatment her friends sent her back to Europe, where she has since died.

There is nothing in the literature of the action of normal heterologous serum like this; it appears to me unreasonable to suppose that such effects can result except from a specific antibody.

*Cases Treated After Primary Operation.*—Of the thirty-nine cases treated with autogenous or stock serum (or both) after primary operation it must be noted that my work has been little advertised, and that the natural tendency of surgeons after a complete and clean primary operation is to hope for the best and trust to the operation alone for cure, only referring their cases when such hope is manifestly gone. Consequently my "primary" list is a relatively unfavorable one to begin with.

Furthermore, the amount of growth left behind, and its circulatory accessibility (bone, lymph-nodes, scar-tissue) is always in a measure conjectural, and the correct dose of the anti-serum (quantitative relation) is correspondingly in doubt. This I believe to be the main cause of failure when failure has occurred.

However, if we count out four cases in which a large and rapidly growing tumor recurred in the wound within three weeks following the operation (before any serum was available), and three more in which liver and spleen were already enlarged when the operation was done, there have been seven failures. I might try to explain these away, but it looks fairer simply to admit them as failures.

Of the successful cases those not recurring in nine months, of course, prove little, but with some among the apparent cures (all of them called by the surgeons "bad cases") the time elapsed since operation is two years, one year and eleven months, two years and two months, two years and five months,

two years and eight months, two years and one month, two years and nine months.

Several of these are of unusual interest.

No. 16 (Miss L., Dr. R. M. Rawls) had a relatively small cancer of the breast, which had, however, spread extensively in the axilla, and was removed only with great difficulty (Halsted operation). She received the serum intravenously without the slightest clinical reaction, not showing even a rash. She was reported in health twenty-one months after operation. Dr. Rawls thinks she is still well.

No. 19 (Dr. W. M. Ford, July, 1911) had a tumor of the breast which weighed, when dissected out cleanly after operation, nearly 2 pounds. She was in perfect health when last heard from and at work in a New York department store.

No. 5 (Dr. L. G. Baldwin) had a large malignant ulcerated breast tumor, numerous glands, and marked cachexia. Dr. Baldwin writes me recently: "She has gained 25 pounds and feels perfectly well, though it is now two years after her operation. I never saw such a result in the years before I used your serum."

No. 31 (Mrs. S., Dr. Baldwin, Brooklyn, and Dr. Harris F. Brownlee, Danbury, Conn.) had a cancer of the sigmoid. In March, 1912, Dr. Baldwin had done an exploratory incision at the Skene Sanitarium in Brooklyn and had refused to operate, seeing that the growth could not all be removed. After hearing of my serum he telephoned last May and asked if I would undertake the case. I reluctantly consented. She had a makeshift operation (about five-sixths of the tumor being removed) in the same month and received auto and stock serum in June, July, and September of the same year. Dr. Baldwin wrote of her recently: "She has gained 20 pounds and is perfectly well. The sigmoidoscope discloses no structure. If this case does not recur the cure will be certainly due to the serum." Dr. Brownlee has kindly informed me in the last few days that she is still in perfect health.

No. 38 (Dr. Austin Flint, Jr., and Dr. W. M. Ford) was reported by Dr. Ford in the MEDICAL RECORD more than a year ago. She had a uterine cancer, recurring in the bladder after operation. The original uterine mass was cut up and sectioned by Dr. Ira Van Gieson, who reported his sections as showing undoubted cancer (signed letter). The indurated mass, persisting in the vesicovaginal wall after operation, was reported by Dr. Alfred T. Osgood as recurrent cancer (cystoscopic examination). This patient's recovery was rapid and entirely satisfactory, pain, induration, and strangury disappearing entirely in three or four weeks, after five injections of stock. A few weeks before Dr. Van Gieson's recent unfortunate death I saw him again about this diagnosis, and he repeated that there could be no question of its correctness, that the specimen had been one of unusual interest and that he had studied it carefully. I see no reason for the skepticism expressed by one or two subsequent medical writers about this case except that the patient recovered. All the physicians who actually saw her (a dozen or more) before and after treatment were deeply impressed.

As to the propriety of publishing this report there are arguments pro and con. It is true that the cases believed to be cured are not yet sufficiently tested by time and extravagant claims may prove unjustified. On the other hand, this report states nothing but facts, and unless the exact limitations of the serum treatment are carefully set forth I shall continue to receive only the moribund and hopeless cases, and doubt and discouragement will be the only results for some years to come. I have therefore decided to publish it simply as a statement of progress to date.

133 EAST SIXTY-FIRST STREET.

## THE ROLE OF EXERCISE IN THE TREATMENT OF VISCEROPTOSIS, WITH SPECIAL REFERENCE TO THE SYSTEM OF W. CURTIS ADAMS.*

BY STELLA S. BRADFORD, M.D.,

MONTCLAIR, NEW JERSEY.

IN reading the medical journals one is tempted to ask which is more truly the burning question of the hour, visceroptosis or psychotherapy, and one also wonders whether the latter is necessitated by the former.

In this study of visceroptosis I shall make no reference to symptoms. It may suffice to state that they include all symptoms known to the profession. The etiology of the acquired cases must, however, be considered, if treatment is to be at all rational.

That the viscera shall remain in place is provided for in four ways: (1) By ligamentous attachment. Each organ of the abdominal cavity has ligaments formed by thickened folds of peritoneum, in some instances combined with muscular tissue, which attach it to the posterior abdominal wall. (2) By adjustment to contiguous structures. Each organ is fitted to the organs and structures with which it is in relation laterally, and above, and below. For instance, the lower surface of the liver takes its form from the structures below it. The duodenum seems moulded over the head of the pancreas. The kidneys get their firmest support from the structures which touch them laterally and to whose shapes they are adapted by layers of fat. (3) Intraabdominal pressure. According to the researches of Dr. Haven Emerson, there is a positive pressure, that is, a pressure greater than atmospheric pressure, within the abdominal cavity, equal at all levels, and exerted equally in all directions. The chief factors in maintaining this are the tone of the diaphragm, the tone of the anterior abdominal walls, and the tone of the pelvic floor. Granted that this exists, it is easy to see its effect on a suspended organ such as the stomach, or colon, or uterus. Such an organ rests on this pressure as a solid body floats in water. (4) A position of poise. Dr. Joel E. Goldthwaite, in his article on posture, has given a most graphic description of the attitude of poise. The chief factors mentioned are the erect head, high chest, flat abdomen, spinal curves slightly convex backward in the dorsal region, and convex forward in the lumbar region, the axis of the pelvis at right angles to the plane of the brim of the pelvis and 60° from the horizontal, tense Y-ligament, tense iliopsoas and hamstring muscles, straight knees, with tense calf muscles, and the weight borne by the forward part of the feet. Muscles of neck and back, chest, and abdomen are in slight contraction, but none is strained. In this position, because of the forward slant of the dorsolumbar spine, and because of the arrangement of the posterior abdominal and pelvic

*Read before the Brooklyn Society of Internal Medicine, November 27, 1913, and before the Brooklyn Medical Society, December 19, 1913.

muscles and fat, making the anteroposterior diameter increase from below upward, being least opposite the fifth lumbar vertebra, the stomach, liver, kidneys, spleen, and pancreas, are supported, as it were each in its own compartment on a slanting shelf. Similarly, because the chest narrows, as an inverted cone, towards the lower part, the liver and stomach are largely held by its walls. Moreover, in this position, the pelvic cavity is largely posterior to the abdominal cavity, and the weight of the abdominal organs falls upon the anterior abdominal wall, and upon the slanting posterior wall, and not upon the pelvic organs.

A loss of poise, with the head dropped forward, sternum depressed, chest flattened, neck muscles straining to hold up the falling chest, of necessity invalidates the other visceral supports. If there is increase of the lumbar curve, though the spinal support remains, the abdomen is shortened, the abdominal walls relax and protrude, and the intra-abdominal pressure becomes negative. If the lumbar curve is flattened, with the resultant thigh and knee flexion, in addition to the loss of the support of the intraabdominal pressure the abdominal viscera lose their spinal support, and their weight falls directly on the pelvic viscera.

This physical condition underlying visceroptosis should be classed as a final cause. Back of it are what might be called contributing causes. These include habits of standing, sitting, and walking, of dressing and of working. These contribute to but will not actually cause a loss of poise, and visceroptosis.

Back of the contributing causes again are the secondary or predisposing causes. These are overeating or drinking, causing dilatation and prolapse of the stomach and intestines; sedentary life, with the weight of too much fat; malnutrition, with its flabby muscles and loss of the fat which should form the adjustment between organs; too many pregnancies, destroying abdominal walls, and structural poise.

But back of all these are what might be called the psychological, the fundamental causes. These might be summarized as life in which the impossible is attempted; life in which there is not enough of daring, of claiming of responsibility; life overwhelmed by the nearness of a too dominant personality; life deadened by continued disappointment in love or ambition; life powerless because of lack of adjustment between heritage, training, and daily living; life spent in a past of sex or drug excess or in dreams of past or future greatness rather than in present day actualities. It is these psychological causes which are fundamental. In the last analysis they are responsible for the protruding chins, the depressed chests, the weak backs and abdomens, the flexed thighs and knees, which seem to be the result of bad habits of living and working, and which are themselves the final causes of visceroptosis.

The treatment has six divisions: (1) Psychological adjustment. This can not be disregarded for without it no treatment will be effective, but often the process of adjustment must be continued over a period of years. (2) Establishing the details of diagnosis by all the means open to science. The symptoms and appearance of the patient tell the story, but palpation, percussion, and the *x*-rays can give clues to details of diagnosis and a treatment which, as suggested and carried out by Sir Arbuthnot Lane, is transforming prognosis. (3) Treatment of symptoms by cathartics, Russian oil, irrigation, tonics, and diet. (4) Making a place for the viscera. This obviously includes returning the spine to its normal curves, and elevating the chest, with an increase in its anteroposterior diameter, and a broadening of the costal angle. These things can be accomplished of course only by exercise. (5) Returning the viscera to their proper place. This is done manually, as with the kidney or uterus, or by massage of the abdomen. It is done by posture, as in elevation of the foot of the bed, by the Goldthwaite posture after meals, by the knee-chest, and inverted chair positions and headstands. It is done by the passive exercise advocated by Dr. E. M. Mosher. It is done also by those operations involving freeing of evolutionary bands of adhesion, in which Lane has proved so powerful a leader, and of which Bainbridge is so brilliant an exponent. (6) To hold the viscera in place. This has been attempted by binders and kidney pads, which owe their good effect to the reinforcement of the natural intra-abdominal pressure, or where this is lacking, to a pressure transmitted through the abdominal contents. It has been done by the tacking operations, so often ineffective because the causes remain. These are tried most often for the uterus, ovaries, kidney, and colon. But pleating, gathering, and tucking operations are often necessary in addition. The "ostomies" are sometimes essential, and sometimes valuable as a short cut, because most patients can not or will not give the time necessary to undo the evils which have been done, and to prevent their recurrence. Repair operations which restore the integrity of the pelvic floor, or of the abdominal wall, as in the cure of hernia, must of necessity increase the intraabdominal pressure and hence aid in holding the viscera in place.

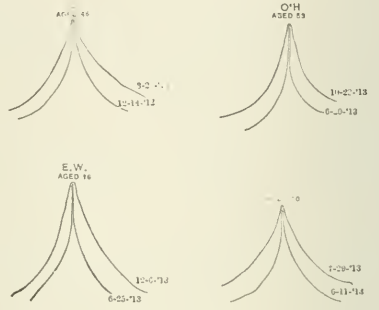
In this scheme of treatment the rôle of exercise is evidently to make place for the viscera, and to hold them in their place. To this end, the effect of exercise both on the bony structure, and on the muscular system should be considered. That it can improve the circulation, and therefore the tone of the organs themselves, and of the general metabolism, goes without saying.

As to the effect on structure. Exercise can make the spinal column flexible, thus making possible a return to the normal curves and hence a shelf on which the viscera may rest. It can make the chest flexible, can elevate the anterior chest wall, can elevate the ribs, and widen the costal angle, making space in the upper abdomen for the viscera. Moreover, it can make flexible the shoulders, thighs, hips, and knees, without which flexibility a position of poise is impossible. Exercise can improve muscles. By improving the muscles of the back, abdomen, thighs, and calves, a person gains the wherewithal to maintain poise. By developing the quadratus, the psoas, and the iliacus, shelves and compartments are provided for the support of the viscera. By improving the quadratus, the psoas, the muscles of the anterior abdominal wall, especially their transverse fibers, the muscles of the pelvic floor, and the diaphragm, intraabdominal pressure is increased. By improving the intercostals, and especially the diaphragm and the transverse abdominal muscles, the chest is elevated and held in a position of poise. One naturally asks, what exercises will accomplish this? My experience in following the work of Mr. W. Curtis Adams along these lines in his sanatorium in Pompton, New Jersey, is responsible for this paper. I will therefore describe a few of his exer-

cises, telling some of the main things accomplished by them.

1. The exercise called "scissors." The patient lies on his side, with arms lightly but completely extended, and thighs and legs extended. From this relaxed position he raises his feet from the floor, and, keeping the position of extension, swings one forward and the other backward, alternating rhythmically. This exercise involves practically all the muscles of the back, abdomen, pelvis, and thighs, but those most involved are those most often slighted in ordinary life. To take the position and hold the feet from the floor requires, for most people, the use of the abductors of the upper thigh, and adductors of the lower, yet the muscles most called on are the external and internal oblique and transversalis in their lower fibers, and the quadratus, the latissimus dorsi, and erector spinæ of the upper side. A person ideally constructed could, however, lie in this position with almost no muscular effort, and the exercise, done with a relaxed and receding abdomen, would be accomplished as lightly and easily as a pendulum accomplishes its swing. The exercise itself, as done by patients, is a flexion and extension of the thigh on the pelvis. The flexion involves mainly the psoas and iliacus, and, to a lesser extent, the upper anterior muscles of the thigh proper. The extension involves chiefly the gluteus maximus, the semimembranosus and semitendinosus. Since, however, the motion of the thigh is so free, its weight tends to carry the pelvis, also, forward and backward. This is resisted by the reverse action on the other side. Hence this exercise becomes really a resistance exercise of pelvic flexion and extension, and the muscles most developed are those most needed in poise, namely the anterior abdominal muscles, the erector spinæ and latissimus dorsi, and those of most value in the support of the viscera, namely the quadratus lumborum, the psoas, and iliacus. That radical changes can be accomplished in the spinal curves by this exercise is shown in the accompanying charts. What this exercise can accomplish for prolapsed abdominal and pelvic viscera, if done in the headstand position, can readily be seen.

2. The second exercise to be described is "pumping." A beginning patient lies on his back with knees flexed, and all his muscles relaxed. Pressure is made at some point of his abdomen, and he is told to inhale at that spot. The position of the pressure is changed and he is again told to inhale. Then he does the same, using his own hand to localize the spot. Gradually he learns by his breath to lift just that part of the abdominal wall indicated, gradually the chest becomes more flexible, falling with each inspiration, rising with each expiration. The costal angle widens, the ribs are elevated, and the anteroposterior and lateral diameters of the chest are increased. That there is more space for all the thoracic as well as abdominal viscera is a natural consequence. Moreover, the increased tone of the diaphragm and abdominal walls of necessity increases the intraabdominal pressure, and this in itself tends to hold the organs in place. The accompanying charts showing changes which this exercise has made in costal angles give an indication of the other changes also accomplished.



The explanation of this exercise is as follows: Since the diaphragm and anterior abdominal walls are both controlled by the respiratory center, the contraction of the one and relaxation of the other readily occur together, the abdominal wall being pushed outward by the pressure of the diaphragm transmitted through the abdomen. Pressure helps localization, and gives the effect also of a resistance exercise. Moreover, in expiration it supplements weak abdominal muscles, and increases the intraabdominal pressure which is transmitted to the diaphragm making it taut over the organs it presses upon as a fulcrum, and so arching the chest as a bow is arched by a taut string. When proficiency in this exercise is obtained, the bulging of the abdominal wall takes place only in the upper part, the break in the recti coming in the line of the aponeurotic band. The lower part of the abdomen is held firm by the passing of the aponeurosis of the external and internal oblique and transversalis in front of the recti. By this contraction of the lower abdomen the intraabdominal pressure is increased, and by the limitation of the bulging of the abdominal wall to its upper third, the pelvic organs are guarded from the transmitted downward pressure of the contracting diaphragm.

3. "Rotation" is the next exercise for consideration. The patient begins as for pumping. He is then told to execute a circulatory motion in his upper abdomen, raising it on inhalation and lowering it on exhalation, first clockwise and then counterclockwise, the plane of the clock face being at right angles to the longitudinal axis of the body. He is usually slow in accomplishing this. After he has

learned to do it, and to do it with legs extended and toes together, it will be found that, though his attention is still fixed on the upper abdomen, he is using all the muscles of his back and abdomen and of his upper arms and thighs, that his chest is moving freely, and that the play of the vertebræ on one another is constant, making correction of any deformity which has not involved bone tissue a possibility. The factors taken advantage of in addition to those used in pumping are: *a.* The asymmetrical shape and attachment of the diaphragm, by which a tendency to an irregular rotatory motion is the natural result of a pull started in any one direction. *b.* The unused transverse fibers of the abdominal muscles. *c.* The interdigitation of the origin of one muscle with the attachment of its neighbor, necessitating, in a position of relaxation, motion of the second if the first contracts. If the diaphragm moves, so must the transversalis. Motion of this necessitates motion in the internal oblique and external oblique, this of the serratus magnus and of the latissimus dorsi, this of the trapezius, and so on, up and down, forward and backward. Moreover, if one muscle contracts with the body relaxed, equilibrium is maintained by the action of its opposing muscles. In other words, there is no limit to the amount of development possible from this exercise even in the very weak or partially paralyzed.

4. One other exercise should be mentioned, and that is the "bicycle." Lying on his back with his feet in the air, the patient flexes his thigh, then his leg, then his foot, then extends his foot, then his leg, then his thigh, doing at the same time the opposite on the other side. In addition to strengthening the muscles of flexion and extension, this will accomplish much in rendering flexible the ankles and knees, chiefly by lengthening the Achilles and hamstring tendons and thus making possible a position of poise. Moreover, if the abdominal muscles are relaxed, the abdominal viscera will be elevated by transmitted pressure.

Certainly the sequence of emphasis in the use of exercise in the treatment of visceroptosis is as follows: (1) Render joints flexible whether the rigidity is due to adhesions, poor circulation, or tense muscles. (2) Render the chest flexible whether its stiffness is due to lack of circulation and nutrition of bones, cartilages, joints, or muscles. (3) Strengthen the back muscles. (4) Strengthen the abdominal muscles. (5) Strengthen the diaphragm.

I might thus summarize the principles underlying Mr. Adams' work: A chain is as strong as the weakest link, therefore attend to that link. Visceral, circulatory, respiratory, mental, moral, and spiritual tone varies with the tone of the diaphragm. Without a good back, a good diaphragm is not available. In a position of rest, advantage can be taken of muscular interplay, and of the fact that no great strain can come to a muscle working against the muscle which naturally opposes it. In a position of strain, that is in the erect position, the action of muscles in the spasm of strain has to be contended with, and overcome. What one gets for himself he has to keep.

In conclusion I would express my very great debt to Mr. Adams for what I have learned of diagnosis and treatment through his knowledge of normal and pathological structural and muscular conditions. Moreover, I would make a plea to physicians not that they all use these exercises, but that they learn to employ as much skill in recognizing structural and muscular pathological conditions as in detecting disease, and that such conditions, when recognized by them, be considered not final but remediable by a system of exercises involving muscular education and coordination, and adaptable to the individual needs.

29 Crescent Street.

## HAS THE TUBERCULOSIS DEATH RATE DECLINED RECENTLY?

By THOMAS J. MAYS, M.D.,

PHILADELPHIA, PA.

A FEW days ago, while interested in a collateral subject I consulted the Transactions of the Ninth Annual Meeting for the Study and Prevention of Tuberculosis (1913), and inadvertently found in it an address by Dr. Frederick L. Hoffman of Newark, New Jersey, on the decline in the tuberculosis death rate from 1871 to 1912. In the introduction of this address he takes great pains in counselling his audience on the vital importance of employing trustworthy methods in all statistical investigations, and incidentally states that he was moved to give this advice on account of an article which he read recently, and which he denounced as "a grossly misleading attack upon the national and, in fact, the world-wide campaign against tuberculosis, based upon absurdly fallacious calculations, unsupported by an appeal to facts," and in which an attempt is made to show that tuberculosis "is not contagious, and that it has not been decreased at all by the measures adopted to combat it during the last ten or fifteen years."

I take pleasure in confessing that I am the author of that article,* and plead guilty to the last charge, and since Dr. Hoffman evinces a lingering feeling that the statistics which I quote are unreliable and untrustworthy, I shall take the liberty of subjecting his own to the same methods that I applied to mine and find out whether they lead to conclusions different to those which I deduced in my article.

Whether the present crusade has reduced the mortality from consumption or not is only to be ascertained by comparing the death rate of this disease while it has been in operation, with a like period of the same before it was called in vogue. This crusade came into existence in the middle or the late nineties; therefore, fifteen years before the latter period and fifteen years after it will cover the whole period to be investigated (1882 to 1911). The average death rate of the first five years of that period supplies the first base of observation; that of the five middle years (1895-1899) gives the middle base, and that of the last five years furnishes the third base. (In some of the localities ten years are substituted for the five-year averages.) Throughout this paper the figures are first reduced to a per mille, and then to a percentage basis. The first interval is between the first and second, and the second interval between the second and the third base.

Dr. Hoffman's address contains more than twenty different statistical collections on the mortality of consumption in America and Europe, giving a mass of material which is based on an aggregate population of over 175,000,000, dating back a hundred years, and is truly a great testimonial to his diligence and industry. Of these I made an analysis of ten, which will be presented in the table below,

*"Effect of Present Prevention on the Spread of Consumption," Medical Record, November 30, 1912.

and will, I think, explain itself, in connection with what has already been said:

DEATH RATE OF TUBERCULOSIS OF THE LUNGS IN THE LOCALITIES INDICATED

| Name of Localities | Per Mille Death Rate First Base | Per Mille Death Rate Second Base | Per Mille Death Rate Third Base | Per Mille Decrease in Death Rate First Interval | Per Mille Decrease in Death Rate Second Interval | Total per Mille Death Rate Decrease | Total per Cent of Death Rate Decrease | Per Cent. Decrease in Death Rate First Interval | Per Cent. Decrease in Death Rate Second Interval | Per Cent. of Decrease in Death Rate in Favor of First Interval | Per Cent. of Decrease in Death Rate in Favor of Second Interval |
|---|---|---|---|---|---|---|---|---|---|---|---|
| Thirty to fifty American cities | 2 80 | 2 15 | 1.86 | 0 65 | 0 29 | 0 94 | 33 57 | 24 27 | 10.35 | 13.92 | None |
| Massachusetts, Rhode Island and Connecticut | 2.61 | 1 97 | 1 46 | 0 65 | 0 51 | 1 16 | 44 44 | 24 51 | 19 53 | 4.98 | None |
| Large German cities | 3 23 | 2.29 | 1.79 | 0 94 | 0.50 | 1.44 | 46.13 | 30 00 | 16 00 | 14 00 | None |
| Southern whites in American cities | 2 85 | 1 94 | 1 59 | 0.91 | 0 39 | 1.30 | 45 61 | 31 92 | 13 69 | 18.23 | None |
| Southern colored, in American cities | 6 35 | 5 06 | 4 30 | 1 29 | 0.76 | 2 05 | 32 12 | 20 21 | 11 43 | 8 78 | None |
| New York, Philadelphia and Boston | 3.40 | 2.51 | 2.13 | 0 89 | 0.38 | 1 27 | 37 35 | 26 96 | 10.38 | 16.58 | None |
| New York City | 3 72 | 2.70 | 2 24 | 1 02 | 0.47 | 1 49 | 40 03 | 27 44 | 12.62 | 14.82 | None |
| Philadelphia | 2.82 | 2.18 | 2 07 | 0 64 | 0.11 | 0 75 | 23 80 | 20 30 | 3.49 | 16.81 | None |
| Boston | 3.66 | 2.58 | 1.85 | 1 08 | 0.73 | 1 81 | 49.46 | 29.40 | 19.94 | 9.46 | None |
| England and Wales (all tuberculous diseases) | 2.43 | 2.01 | 1.65 | 0 42 | 0.36 | 0.78 | 32.09 | 17.27 | 14.81 | 2.46 | None |
| Total average of above | 3.38 | 2.53 | 2.09 | 0.83 | 0.44 | 1 29 | 38 46 | 25.30 | 13.17 | 12 12 | |

In the above table the first and third columns designate the beginning and ending of the thirty-year period under observation, and the second column represents the time when the prevention campaign was introduced; therefore the interval between the first and second columns marks the time when no special efforts were made to diminish consumption, and the interval between the second and the third column covers the time when the present prevention campaign was in its swing. The fourth and fifth columns indicate the per-mille rate of reduction which took place during these two intervals. The eighth and ninth columns show the same differential rate of reduction between the two intervals in the shape of percentage figures. The tenth column groups all those localities which give the greater per cent. reductions during the first interval, and the eleventh those localities which give the greater per cent. reductions during the second interval. It is rather surprising that all the greater reductions are found in the tenth column.

This table undoubtedly shows that the consumption crusade does not come up to the expectations which its sponsors held out to the public. It may be contended, however, that this is true only of ten of Dr. Hoffman's localities out of a possible twenty-four, and that the remainder may put a different phase on the matter. In reply to this it may be said that all of them were subjected to the same test, and were found to tell the same story except the collection of the mortality of all the tuberculous diseases in England and Wales. Here it developed that there was a greater decrease of one-third of 1 per cent. in the female population in the second than in the first interval, but the aggregate of both males and females shows a 2.25 per cent. greater decrease in the first than in the second interval. It must be borne in mind here that this collection includes all other tuberculous diseases, besides those of the lungs, and is not altogether pertinent to the subject.

Now if one thing stands out more prominently than another in this whole investigation it is the uniform and overwhelming evidence that the present prevention crusade is not only a failure as a prophylactic measure, but really a provoker of the disease, inasmuch as the aggregate figures plainly show at the bottom of the table that its death rate was 11.22 per cent. higher at the end of the second interval than it was at the time when the crusade began. And if Dr. Hoffman was justified in condemning my investigation of a year ago so unsparingly as he did, does he not think that he is bound to visit his own conclusions with greater condemnation, because they make out a much stronger case against his favorite theory than mine?

Now in view of all the wild claims which are constantly being made in reference to the profound beneficence which this crusade is conferring on the human race, it may seem strange to some that there is such a wide divergence between this attitude and the facts which have been brought to light in the present inquiry. To those, however, who are in close touch with the history of this movement this is no surprise. They realize that its whole fabric is founded on a deep-seated obsession, of which the history of medicine records numerous examples; these, like all similar epidemics, have their day, and then succumb to the inevitable return of sense and reason. If an insignificant number of the prognostications that have been made in the last ten or fifteen years as to what the crusade would do to consumption had materialized, this disease would have become extinct long before now.

1829 Spruce Street.

## A COMPARATIVE STUDY OF THE IMAGINATIVE POWERS IN MENTAL DEFECTIVES.

By HOWARD A. KNOX, M.D.,

NEW YORK.

ASSISTANT SURGEON, UNITED STATES PUBLIC HEALTH SERVICE, ELLIS ISLAND.

Some of us having gazed into the smoke of a choice cigar, or into an open fireplace, may have seen, perhaps, the sweetheart of other days, or the vision of a farmhouse away off in some old country town. This was imagination—the imagery of a cultured mind—and so we shall accept it; but what of these powers in the uneducated, and in those with whom the latter are so often confused, the mentally deficient?

It has been claimed that one of the most essential and the most common details, missing or undeveloped in ordinary congenital inferiors of even the higher grades, exclusive of actual geniuses, was native ability or constructive imagination, *i.e.* the

GROUP OF 25 AVERAGE "NORMALS"

| Case No. | Age | Sex | Impression | Blot No. | Reaction, Time, Seconds | Head | Answer to Stock Question |

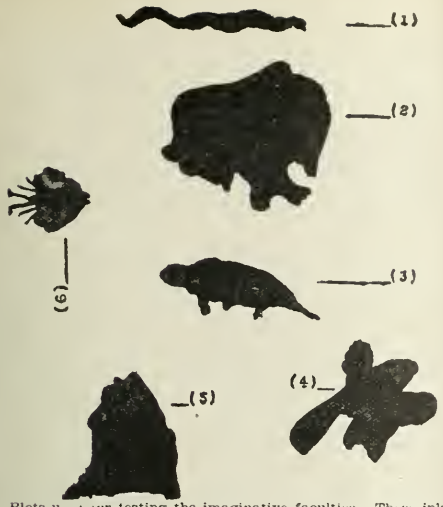
ability to generate new complexes from former percepts and to surmount simple new obstacles without systematic teaching. This contention has been conclusively proven by us in our work with performance tests, which require a small amount of native ability (case tables recorded and available), but, as a matter of interest and to add to our former studies, the following investigations were made: Twenty-five average Italians, from fifteen to thirty years of age, and twenty-five Italians of the same ages who were found to be mentally deficient by our measuring scale for illiterates, were tested with six ink blots, of somewhat indefinite outline, to determine whether logical associations could be formed and whether in the two groups there would be a difference in the degree of judgment shown. In all cases this question was asked: "What do these spots look like and what do they remind you of?" The answers obtained from the two groups will be recorded, as will the mental ages by our scale, of the members of the defective group. The exact answer given by each alien to the stock question asked about each of the six blots will be recorded in the tables so that one may draw a detailed comparison between the two groups. The blots were shown to the immigrants in the same position that they appear in the illustration. All are illiterate, and none have been away from Italy before. The heading "impression" in the tables denotes the impression made on the mind of the examiner by his inspection of the alien's face; "Blot No." indicates the number of the blot in the illustration. Notations made under the heading, "Reaction Time" (a point upon which much stress has been laid by psychologists), show time elapsing between the end of the question and the beginning of the reaction or answer. "Head" notations denote whether the alien possessed more than the ordinary amount of asymmetry of face and head.

During the course of the experiment, as a matter of satisfaction and interest, twelve American men, between the ages of twenty-five and thirty-five, with common school educations, were tested on the blots with the results recorded in the tables presented above. The reaction time in all cases was less than four seconds.



Blots used for testing the imaginative faculties. These ink blots were designed for the purposes of a comparative study of the associative and constructive imaginative powers of normals and defectives among aliens. Each was intended to resemble vaguely a number of common objects, for instance (1) might cause one to recall a snake, a pennant, a rope, or a river (depending on his experiences); (2) an animal or a map; (3) a lizard, a mouse, or a rat; (4) a leaf, a flower, or a cloud; (5) a house or a hay stack; (6) a strawberry, butterfly, or an umbrella.

| Case No. | Blot No. | Answer to Stock Question | Case No. | Blot No. | Answer to Stock Question |
|---|---|---|---|---|---|
| 1 | 1 | A snake | 7 | 1 | An eel |
| | 2 | A map or a lake | | 2 | Picture from "Alice in Wonderland" |
| | 3 | A lizard | | 3 | A gila monster |

| | 3 | A rat | | 3 | A prairie dog |
| | 4 | A sea plant | | 4 | A leaf |
| | 5 | A shack | | 5 | A house |
| | 6 | A crab | | 6 | A bouquet |

It has been the policy of the writer in presenting this paper to avoid all complicated technical terminology in order that its contents may be of service to those outside of medicine and psychology who are interested in social or other work upon which this may have a bearing. The cases are perhaps not numerous enough to draw trustworthy conclusions from and no attempt at psychanalysis was made to determine why each individual gave the answer that he did. Keeping these factors in mind, therefore, these fifty cases seem to warrant the following conclusions:

1. It is apparent from a study of the tables that there are no Jules Vernes among the twenty-five defectives, at least, and, as compared to the twenty-five normals, there is very little ability to draw mental pictures from commonplace or amorphous objects.

2. The associations among the defectives are for the most part not logical; for instance, blot (1) would hardly recall a skull to a normal person.

3. Asymmetry of the face, head, or both, was present more often in the defectives than in the normals. This is our usual experience in the routine work at Ellis Island.

4. The reaction time averaged nearly twice as long in the defectives as in the normals, being 6.3 + seconds in the former and 3.7 + seconds in the latter.

5. Tests of the imagination and the average reaction time to questions may be valuable points to consider when dealing with mental defectives from a diagnostic standpoint.

I wish to thank the officers at Ellis Island for their kindness in furnishing me with the proper material for this experiment and for having tested out the twenty-five defectives to determine their mental ages.

## RECENT ADVANCES IN THE STUDY OF THE PATHOGENESIS OF CANCER.*

By M. J. SITTENFIELD, M.D.,
NEW YORK.

From the study of the occurrence of spontaneous tumors in mice and rats, and their transplantability, clinical behavior, and pathology, a more intelligent understanding of the entire subject of malignancy has resulted. Some of the newer work which has appeared within the past two or three years seems quite important and may possibly throw some light upon the vague ideas of pathogenesis which now exist. Certain findings which may be accepted as reliable and which bear upon the etiology of cancer, seem by analogy with human cancer to be of great interest. There is very little doubt that cancer of the mouse or rat is entirely comparable with that of man, since it exhibits continuous infiltrative and invasive growth, also the power to metastasize, to cause cachexia, to recur after removal, and finally to result in death of the animal in about one-thirtieth the time of its entire life cycle. The relation between embryonal and cancer tissue has been studied by a great many. Fichera inoculated rats subcutaneously with a suspension of rat embryos, causing nodules which grew progressively until at the expiration of two or three months they had acquired twenty times their original size. By the end of six months, however, their epithelium had greatly diminished so that the nodule could not be considered in any sense a malignant growth.

The question whether pregnant animals may not perhaps offer a more favorable soil for the growth of embryonic tissue was investigated by Askanazy and his pupil Jentzer. They thought that pregnancy in the host exerted a favorable effect upon the growth of experimental teratoma in white rats. Rous afterwards established the fact that embryonic grafts grew better in rats, from which the embryos had been removed, than in non-pregnant or other pregnant rats; on the other hand, when an animal still bearing embryos was inoculated with embryonic tis-

*Read before the Eastern Medical Society, December 14, 1913.

sue from her own uterus, the grafts failed to grow or to differentiate in spite of the fact that they became vascularized; the graft, however, retained its vitality, and moreover after pregnancy was concluded continued to grow. Freund also noticed the stimulating effect of pregnancy upon the growth of rat embryo, although no difference could be discerned between the outcome of homoplastic and that of autoplastic transplantation.

The comparative growth rate of malignant cells has been studied very carefully by Bashford. He weighed mice embryos at different periods of gestation, comparing them with a corresponding weight of tumor. When he estimated the proliferating activity of the two tissues, it became evident that while some tumors attain the rate of growth possessed by the embryo, most of them fall far below it.

The relation of heredity has been studied lately in rats or mice by Bashford, Murray, Tyzzer, Levin, and myself. These animals lend themselves very readily to heredity experiments; they are short-lived and rarely live to be over two years old. Bashford and Murray crossed mice affected with spontaneous tumor, with the offspring of cancerous parents, and obtained strains of mice in which the cancerous heredity ranged from 75 to 90 per cent. Tyzzer arrived at similar conclusions; he observed the frequency of tumor development in the descendants from three female mice suffering from malignant tumor. Levin and myself crossed tumor resistant male and female rats and inoculated Ehrlich's rat sarcoma into 23 of their offspring and in only five (or 25 per cent.) did the tumor grow; in 20 other normal rats which were used as control 86 per cent. were positive to tumor inoculation; in other words, the results were in accord with Mendel's law of heredity.

Lathrop and Loeb have reported in a very recent publication observations upon the frequent occurrence of mammary tumor in mice. Animals raised in the same breeding establishment under the same condition of climate and feeding showed different percentages of cancer of the breast, depending upon the strains of their ancestors. The age at which the tumor developed differed also in the various strains; in some it appeared at the age of twelve months or below; in other strains the maximum was reached between fourteen and twenty months; the very youngest in which a tumor was first observed was five and a half months. In mating a strain rich in tumor with a strain very poor in tumor, they observed hybrids which were rich in tumor.

In Haaland's examination of 288 mice with spontaneous tumors, only six were males and of the 353 tumors detected 311 were mammary adenocarcinoma; this could not be attributed to vigorous physiological functional activity alone, as of 74 mice which developed mammary tumors and had been observed since birth, only 33 (or less than half) are recorded to have littered prior to the development of the tumor, while no litter is recorded for the other 41. In one of these animals Haaland reports that while the absorption of a spontaneous tumor was under way, another was growing progressively at the same time and producing large metastases in the lungs and liver.

The mechanism and formation of metastases of tumors was first investigated by Levin and myself. We injected tumor emulsion into blood vessels or joints, with a view of ascertaining the transportation and formation of metastastic growth in distant organs. In mice and rats metastases occurred through the blood vessels and rarely, if ever, by the lymphatics. After subcutaneous inoculation metastases are rarely encountered. We observed the following interesting result: A Flexner-Jobling rat carcinoma upon intravascular injection, found lodgment in the lungs; the mouse sarcoma when injected into the rat produced metastases only in the liver. Ehrlich's rat sarcoma failed to give metastases anywhere. In each instance normal animals were employed and the method of transportation was identical. It would seem therefore that there is a specific affinity or an interrelation between the different cancer cells on the one hand and the susceptibility of the cells of certain organs on the other. The cultivation of cells outside of the body has proven of great aid to the cancer workers. Harrison was the first to show that the nerve tissue of a frog embryo could be grown in lymph *in vitro;* plasma was substituted subsequently by Burrows and Carrel, and observation on connective tissue cells showed that they were able to keep them alive for 85 days, also that fragments of the chicken heart pulsated after three months. Lambert and Hanes conducted comparative studies on cancer and normal connective tissue cells and described a more rapid cell division, a greater activity, and a more marked ameboid movement of sarcoma cells when compared to normal cells.

In the experience of the majority of investigators, it is essential for the effective transmission of a tumor that living and intact cancer cells be introduced into an animal of the same species, or into one that is very closely related. The proliferation of a tumor after its introduction into another host is an example, not of infection, but of transplantation; the parenchymal cells of the resulting growth are derived from the elements of the implanted tissue, and not from the tissues of the new host. It is obvious that the malignant growth is caused by an unlimited proliferation of cells, but what is not definitely known is the factor which causes this power of unlimited growth. That mechanical stimulus (or reiz) as trauma causes cancer seems to be fairly well accepted by many. Alleged instances are cancer of the cheek in natives of India occurring frequently as the result of chewing of the betel nut. Cancer of the abdominal wall occurs in the natives of Kashmir from wearing a Kangry basket under their robes; other examples are cancer of the scrotum in chimneysweeps, and cancer of the skin in tar workers. An example of physical trauma is the *x*-ray cancer; the careful dosage of cathode rays retards superficial growth; in large doses, however, these same rays cause burns and skin ulceration, which may develop eventually into cancer. The latest statistics by Hesse report 64 *x*-ray cancers. In these *x*-ray cancers the relation of reiz (or stimulus) to cancer can be closely traced. The cancer develops from the skin ulceration, the epithelium being converted into cancer cells, and it is of interest to note here that once cancer has started it becomes independent of the original stimulus. If the cancer is excised and the *x*-ray influence removed, the cells in the adjacent and neighboring tissues which are evidently healthy turn into cancer cells. It is impossible to reconcile an *x*-ray cancer with our older notions of the so-called performed embryonal theory. The facts would point rather to Ribbert's notion, that every epithelial cell in the body may become a cancer cell, *i.e.* a simple inflammation of the subepithelial tissue may change the epithelial cell so that the original resistance against unlimited proliferation is dis-

turbed. Sunburns may in some cases cause cancer to develop as for instance xeroderma pigmentosum.

Considering these two kinds of cancer development, we must realize that they do not fit our previous theories of pathogenesis except perhaps the parasitic one. All sorts of parasites—bacteria, blastomycetes rhizopods, protozoa, sporozoa, and other kinds of vegetable and animal life—have been accused of being concerned in the etiology of cancer. The view that some parasites play an intermediate part, causing chronic irritation, has of late received strong support.

Borrel has consistently upheld the existence of a cancerous virus; he has always insisted that transplanted tumors represent the second stage in the development of cancer, because this was preceded by a transformation of normal cells into malignant elements. He succeeded in demonstrating cestodes and nematodes in the tissues adjoining young adenocarcinomata in mice. These worms were found in the groin or axilla of mice affected with cancer of the breast. Similar helminthes have been discovered in the lungs and lymph nodes, as well as in the circulation of mice suffering from generalized lymphomata. Four years ago Borrel reported a rat cancer which he propagated through three generations, the malignancy of which he attributed to the cysticercus of *Tenia crassicola;* in another case he found a small adenocarcinoma of the kidney enveloping a cysticercus. Similar cases have been reported by Regand, Saul Bidre, and Consi, etc., within the past two years. The acarus has been found in rats and in lymphosarcomata in dogs. Cysticerca are discovered frequently in the liver of mice, and so too sclerostomata in the cancer of horses. *Trichnodes crassicola* has been described in the bladder of the rat (Loewenstein).

The most painstaking and thorough work in this connection is that of Fibiger, which consumed almost seven years, and was published within the last six months. In three brown rats, which had previously been treated with a subcutaneous injection of tubercle bacilli and were kept in the same cage, he found very striking changes in the walls of the stomach at or near the cardiac end, presenting a growth of solid consistency resembling a papilloma. In this papillomatous growth which histologically appeared malignant, nematodes 16 centimeters by 0.25 millimeter were discovered, also the ova containing the embryos. Later he examined 1,144 rats and found a similar condition in 11 and in these he found the cockroach (*Periplaneta americana*) as the intermediate host. In another series of 61 rats from a sugar refinery, similar nematodes were present in the stomachs of 40 animals and in 18 of these morbid changes in the mucous membrane of the stomach were found. In nine the lesions were carcinomatous, whilst the other nine disclosed preliminary stages or precancerous conditions. His further studies convinced him beyond a doubt that these tumors were intimately associated with the presence of nematodes and their ova; that the ova of these parasites came from the *Periplaneta americana.* His efforts were directed towards producing these changes artificially and by feeding rats with these roaches he succeeded in reproducing cancer of the stomach. The development of these tumors was rather slow and in three of them metastases were encountered. In the metastases, however, nematodes could not be demonstrated. This would argue that the tumor of the stomach was able to develop a secondary growth without the presence of the parasite in other organs. From these experiments he concludes that the roach acted as the intermediate host which brought to the stomach of the rat a nematode (spiroptera). This gives off a virus, which in turn causes anatomical changes affecting the mucous membrane; the lesion is one of epithelial hyperplasia and inflammation and in some instances a papillomatous growth resulted which filled the entire stomach. In five rats, however, malignant epitheliomata were found with invasive and infiltrative growth.

The interesting experiments of Rous fit very closely with the subject which is now under consideration; he was able to transmit a chicken sarcoma after a tumor emulsion had been passed through a Berkfeld filter No. 5 medium, which is impermeable to the *Bacillus prodigiosus,* or by means of dried or powdered tissue. When the cell free filtrate or the dried powder diluted in Ringer's solution was injected, the sarcomata appeared at the site of inoculation growing more or less diffusely, but when a little dried washed earth was added to this filtrate, a larger number of growths developed, demonstrating the importance of cell derangement and trauma such as was induced by the needle prick and earth. Metastases occurred by way of the bloodstream and were encountered frequently in the liver, spleen, and heart. In a later communication Rous states that he could successfully transplant the tumor or cell free filtrate into the developing chick embryo in the Plymouth-rock egg.

The work of Fibiger and Rous is by far the most valuable contribution to the pathogenesis of cancer that has been brought forward within the past few years, although a great deal more work is necessary to corroborate these facts and to make them conclusive.

Local predisposition and local reaction are most potent factors in the development of cancer. This has been shown by I. Levin, when he inoculated a Flexner-Jobling tumor into the normal testicle of a rat; it failed to grow in spite of the fact that it grew subcutaneously and when inoculated in different internal organs. But when, previous to the inoculation of the tumor an inflammatory lesion was produced in the testicle, then the tumor inoculation was successful. The question of hyperemia and anemia in the development of cancer has been very much discussed by Theilhaber; he bases his view upon the anemia produced from laceration of the cervix during labor resulting in scarlike and atrophic processes and with these stenosis and atrophy of the blood vessels. He states that these circulatory disturbances of the cervix render it a favorable soil for the development of cancer; the hyperemia in the body of the uterus however during menstrual life, he argues, prevents the occurrence of cancer. This has been entirely discredited by the work of Greischer and Schminke, Fajani, Janowisz, and also myself. The first two induced anemia in one ear of the rabbit by ligating the carotid; in another series of animals they produced arterial hyperemia by cutting the sympathetic; in a third series they ligated the veins at the base of the ear and proved that these disturbances of the circulation played but a small rôle upon inoculation and growth af the tumor. In my experiments a tumor was inoculated into the leg of the rat and twenty-four hours after the inoculation, anemia was induced by ligating the femoral artery; in another set of experiments venous hyperemia by Bier's method was employed. The tumors in the anemic leg grew very poorly and in only 18

per cent. did the tumor develop, whilst the hyperemic leg yielded 90 per cent. and the tumors grew very rapidly. This is entirely in keeping with Moreschi's results, who noticed that the growth of the tumor was retarded in starving animals, and flourished in overfed animals.

If we now attempt to summarize the present status of pathogenesis the first question that confronts us is the following: Is the epithelial or connective tissue cell the main primary factor in the development of cancer? The majority of investigators are agreed, and even Ribbert has modified his opinion of late, that the epithelial cell undergoes biological and morphological changes and assumes cancerous activities, namely: an increased proliferative energy, the property of invasive and infiltrative growth, transplantability, and the power to metastasize.

The fact that in India from constant chewing of the betel nut cancer starts always in the same spot, and that in Europe and America such a form of cancer is hardly known would argue very strongly against the congenital theory. A mouse affected with a spontaneous tumor can be very readily inoculated with its own tumor; on the other hand, it would seem that cancer cells growing in an animal in which they are not native, are doing so under great stress or at least under a certain disadvantage.

(1) Tumor development in animals depends upon local and general conditions, just what these may be has not been fully elucidated.

(2) Exposing the cells for two hours to 50° C. or grinding them in a mortar with sand does not impair their transplantability, nor injure their proliferation or growth energy.

(3) Cancer cells differ from ordinary cells, through their increased energy of growth, and through their power to invade and infiltrate other tissue.

(4) The parasitic theory may be classified with that of chemical poisons; either they diminish or entirely destroy the resistance of the cell against parasitic invasion, or by means of their toxins they may exert this specific stimulus upon the infected cells and induce unlimited proliferation. Against this theory may be argued the ease with which the cancer tissue can be ingrafted into the animal within which it first acquired malignant properties.

Again, some gummata can hardly be differentiated microscopically from sarcoma; the same is true of some lymphomata and leucemic tumors, the etiology of which is not definite, but very probably parasitic.

(5) In addition to the studies of heredity in cancer experiments reported a month ago of Lathrop and Loeb confirm the hereditary factors in the incidence of cancer of mice. It would seem, therefore, that we cannot lay claim to any one particular cause in the pathogenesis of cancer, but that probably many factors collectively must be considered. First: factors which cause a local and a general predisposition or the precancerous stage. Secondly: the direct stimulus which may arise either from within or possibly from some foreign agent.

Medical Services—"Necessaries."—Medical services are necessaries of life which parents are required to furnish their children, and are therefore within the purview of California Civil Code, Sec. 171, as amended, making a wife's separate estate liable for necessaries furnished the family while she lived with her husband.—Evans vs. Noonan (Cal.) 128. Pac. 794.

## THE VALUE OF ACCURATE DIAGNOSIS IN DISEASE.

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

To-day, more than ever, the importance of accurate diagnosis is recognized. Prognosis and treatment are not considered so essential, although formerly they were estimated of quite as much, or of more, value.

This was the day when there was not a little guesswork and when laboratory research was not advanced, even among the most distinguished professors and practitioners of medicine and surgery. Malaria was diagnosed without knowledge of the plasmodium. Diphtheria was affirmed to be present and yet the Klebs-Löffler bacillus had not been discovered. The tubercle organism was an unheard-of quantity, although pulmonary tuberculosis was declared to exist. In these diseases, diagnosis was frequently correct, although the scientific accuracy of our day was lacking.

In other instances, error of interpretation of signs, as symptoms, was established, sooner or later. Do such mistakes occur to-day? Assuredly they do, but not so often as when we seniors were juniors. Is the advance made an unmixed good, or is it allied with some things that are evil, or steps backward? I, for one, believe there are serious drawbacks to later acquisitions. I shall mention a few: We have been latterly, as is now acknowledged by some of our ablest practitioners, prone to be too dependent upon reports from the laboratory. Errors of fact, or interpretation, are discovered, and even among the best trained and most careful workers, in this special field. These errors are finally best controlled in my judgment by the broad and searching medical acumen, which is solely the product of long and large general practical experience at the bedside, as disease becomes manifest either within or without hospital wards. An intelligent and industrious physician, with ample opportunity to observe and to do, may become notably expert in any one special line of work. He cannot as a rule, become a *narrower* authority in more than one. In actual practice we may desire the help of more than one specialist in a given case. But ultimately the all-around family physician, if he has "mens sana in corpore sano," must rule or determine the issue to the great advantage of the health and well being of the patient—physical, moral, intellectual. What is most required to-day is to bring this fact clearly and forcibly to the minds of all men and women. Without this belief and resulting absolute confidence what is the outcome? Some men, alas, pretend to a knowledge they do not really possess; others think they know, but their knowledge is at best imperfect in certain directions, and the best available knowledge is what is most required for the amelioration or cure of disease.

Even with all the knowledge of the schools at our behest disease is happening and uncertain. Time alone, with continued, patient observation and care, will bring about the best results possible, in many such cases.

To me, so-called accurate diagnosis is a misnomer, simply because it deals almost exclusively with signs and symptoms that are judged almost solely with physical methods of research. The personal, individual equation is far too much ignored, or lost sight of completely. Nevertheless, it is this quantity in every man's, or woman's, ailment which is,

if not the primary factor to be considered in the management of disease, at all events one of very great importance in almost every instance. Auscultation, palpation, percussion, mensuration, etc., have been exploited to the uttermost, but they are by no means, combined with other best methods of research, laboratory or physical, all we need. It is high time to cry a halt to their overvaluation. No science, no single expert advice, no series of examinations by experts can take the place of the comprehensive appreciation and doing of the wise, beneficent general practitioner of medicine. He it is who can solace, console; sometimes cure when others cannot. I pray earnestly the day may come again, and very soon, when poor, misguided, ill men and women, may lay to heart the facts stated in a very brief and imperfect way. When that day comes, as it surely will, the family adviser will be duly selected and implicitly obeyed, despite all the specialists brought into the case, even among the wealthiest, most powerful, or important in the world.

## "TANGO-FOOT."

By GUSTAV F. BOEHME, JR., B.S., M.D.,

NEW YORK.

NEUROLOGIST TO THE WEST SIDE GERMAN DISPENSARY AND HOSPITAL; ASSISTANT PHYSICIAN TO THE NEUROLOGICAL INSTITUTE; CLINICAL ASSISTANT, VANDERBILT CLINIC, DEPARTMENT OF NEUROLOGY.

Occupational diseases have been described for a long time, yet it is only recently that a new affliction, due entirely to our love of the esthetic and the joyous, has laid its hold on the pleasure-loving public. We have known of the bursitis, called "housemaid's knee"; we have sympathized with the miner with his "miner's elbow"; the weaver has suffered from that painful condition "weaver's bottom"—and now our feelings must be extended to the cabaret dancer, the little chorus girl—and to the devotees of Terpsichore in general.

I have recently been consulted by a number of dancers who came to me complaining of "pain in the front of the foot," and in every instance have found the same symptom-complex—and on investigation discovered the cause constant—the modern dance. I feel, therefore, that it will not be amiss to report my experiences with this condition.

*Symptomatology.*—The patient generally awakes in the morning with a slight dull pain in the outer anterior aspect of the leg in its lower third. At first it is regarded as a slight bruise or a "little rheumatism." During the next few days the pain becomes more marked and a stiffness in flexion and extension of the foot is noted. Going up and downstairs is painful, especially the latter. He, or she, now becomes worried and seeks medical advice.

The physician on examination notes the slight limp of the patient. He discovers that the patient finds standing on the toes, or passive and active extension of the ankle joint painful. There is no redness. Over the region of the tibialis anticus tendon pressure produces a slight degree of tenderness. With the hand over this painful area, extension and flexion of the ankle is made and the typical crackling feeling of a tenosynovitis is noticed.

*Pathogenesis and Pathology.*—The latter day dances, especially the tango and the maxixe, and to some extent the complicated figures of the hesitation waltz call for great flexibility of the ankle, with much movement at this point throughout the various intricate steps. The more common movements are those of extension, flexion, and adduction of the foot. The resultant is a constant strain on the extensor muscles of the foot, viz., the tibialis anticus, the extensor longus digitorum, and the extensor proprius hallucis, which in turn produces a tenosynovitis in this muscle group. The commonest tendon involved is that of the tibialis anticus.

*Treatment.*—I have to date seen seven cases of this condition, which I do not report in detail because the syndrome is always the same. One case, of the same clinical picture, I saw in a seamstress who worked the sewing machine with her foot—this is not included in this series—but the condition was the same.

Rest is the first requisite. By this I mean rest from the exciting cause. Immobilization with plaster of Paris or with adhesive plaster does no good; in fact the pressure irritates, limits walking, and causes needless stiffness. Simple cessation from dancing is all that is necessary, with a limitation in the amount of walking done.

For the simpler cases massage with alcohol or simple soap liniment is sufficient. If this does not effect the desired result I find that the following prescription painted over the affected tendon daily will quickly remove the pain:

℞ Tr. Aconiti,
Tr. Belladonnæ, āa, ʒii.
Tr. Iodi, ʒiv.
Sig.—Paint daily.

Finally, baking daily for two or three days will remove the effusion in the tendon sheath and restore the limb to its normal.

I call attention to this condition so that it may not be confused with rheumatism, periostitis, or any other local inflammation. It will pay in every instance when the pain is located as described to ask whether the patient be a disciple of one of the light-footed artists who have added so much joy to the world of late—and apparently have developed a minor pain. If so, look for this tenosynovitis of the tibialis anticus and its allied muscle group which I have called "Tango-Foot."

2131 Broadway.

**Psoriasis in a Very Young Infant.**—Haldin Davis reports the case of an infant 8 weeks old, in whom the eruption appeared at the age of 1 month. A very large proportion of its entire body surface is covered with a figured erythema with scarcely any induration, but with a scaly surface. Where the erythema is limited by healthy skin it shows a circinate outline, suggesting the coalescence of circular patches. The face is involved and so also is the scalp, which when the patient was first seen was covered with a thick adherent crust. Most of the surface of the body and limbs is covered, but the extensor aspect is more affected than the flexor, although the exact points of the elbows and knees are not especially attacked. On the buttocks the eruption is complicated by the presence of a certain amount of napkin erythema. The diagnosis in this case lies between psoriasis and syphilis, but the latter is excluded by the following considerations: (1) The baby is perfectly well although it has had no antisyphilitic treatment. (2) There are no other signs suggestive of syphilis. (3) It is the youngest of four children, the ages of the others being respectively 11, 7 and 4. All of them are healthy, and the mother has had no miscarriages. (4) The Wassermann reaction, both in the mother and child, is negative. It is interesting to note that there is no history, as far as can be ascertained, of psoriasis in the family. In most other cases of psoriasis in early infancy there has been strong evidence of heredity.—*Proceedings of the Royal Society of Medicine.*

## HYPOTENSION ASSOCIATED WITH A DEFINITE SYMPTOMATOLOGY.

THE subject of abnormally low blood pressure is not as well known as that of abnormally high blood pressure. It is generally recognized that in cases of acute poisoning by chloral and alcohol, and of chronic poisoning by nicotine, in cases of shock, and in cases of heart weakness, there may be a more or less pronounced diminution in vascular pressure. A series of cases of diminished blood pressure associated with a definite symptom complex was studied by Edward H. Goodman (*American Journal of the Medical Sciences*, April, 1914), who states that with the employment of the auscultatory method all pressures below 120 mm. Hg. should be regarded as low. He classifies the causes of hypotension as follows: "(1) Acute infections, excepting epidemic cerebrospinal meningitis. (2) Chronic wasting diseases: carcinoma, tuberculosis, cachexia from whatever cause, Addison's disease. (3) Hemorrhage, drugs, chloroform. (4) Nervous disease: general paralysis of the insane, neurasthenia, after epileptic seizures, sometimes in tabetic crises, after lumbar puncture, Graves' disease (at times), osteoarthritis, exhaustion, shock—surgical or anaphylactic. (5) Cardiovascular disease: tachycardia, dilatation of the heart, arteriosclerosis (at times), mitral stenosis, decompensatory cardiac lesions. (6) Blood dyscrasias: anemia, polycythemia with splenomegaly. (7) Renal conditions: cyclic albuminuria, nephritis (at times), amyloid disease. (8) Intoxications: alcohol, tobacco, acute adrenal insufficiency. (9) Terminal hypotension preceding death." It is pointed out that the clinical significance of low blood pressure has been clearly recognized in such conditions as surgical and anaphylactic shock and in acute fever. Münzer delineated groups of cases of hypotension associated with arteriosclerosis, with status thymolymphaticus, with orthostatic albuminuria, with chronic nephritis, with paroxysmal tachycardia, and with cachectic conditions.

Goodman describes a series of cases of low blood pressure in which there was no demonstrable organic lesion. These cases were observed mostly in patients in early adult life, in whom the chief symptoms were headache, vertigo, and mental and physical tire. In none of the five patients whose condition was studied by the author was there any evidence of tuberculosis. Autointoxication was ruled out as a possible factor. Neurasthenia was not held accountable for the symptom complex. The author can offer no explanation as to the cause of the hypotension. In the treatment of this condition he instituted a series of simple physical exercises which the patient was directed to employ for at least ten minutes every morning. These exercises were to be followed by a showerbath, at first hot, and then as cold as could be borne. Ascending doses of tincture of nux vomica, beginning with fifteen drops three times a day, were prescribed. This drug was to be continued until a physiological action was obtained. In one patient as much as seventy-five drops of the above preparation was given without the production of any apparent physiological effect. Of course such large doses would be extremely unsafe in the average case. Excessive indulgence in tobacco, alcohol, tea, or coffee was prohibited, and a coexisting constipation was corrected. Under this method of treatment all of the author's patients improved and at the same time there was a corresponding increase in their blood pressure to within the normal limits.

## TREATMENT OF TUMORS OF THE BRAIN.

IN no realm of surgery has more progress been made than in that of the brain. It is not long ago that this region was a terra incognita so far as operative measures were concerned. At the present time, operations are undertaken with the view to relieve certain conditions, and in many cases to save life, with a fair degree of success, which a few years ago would not have been thought of, much less attempted. The present condition of the surgery of brain tumors is well stated in a recent report by Howard H. Tooth. Some of the general conclusions set down in this report were as follows: A high general mortality exists for all operations on the brain, even in the hands of the most experienced surgeons, and unforeseen fatal results follow even the apparently simple trephining. The danger of operation is lowest in the central region and highest in the cerebellar, particularly if the tumor is in the lateral recess. The immediate dangers common to all growths, all situations, and apparently all operations are shock, collapse, respiratory and cardiac failure. These latter may occur any time within 14 days, and sudden cessation of respiration may occur in cerebellar cases which appear to be doing well as late as a month after the operation. This period being passed, the patient may still show no improvement, may develop added symptoms indicating unchecked growth of the tumor, increasing hernial protrusion, drowsiness or coma, and in some cases a progressive asthenia and emaciation. In favorable cases progressive improvement in all respects takes place immediately after operation, the further progress of the case depending upon the nature of the tumor. Practically the tumors are of three types, highly malignant from the first, or becoming so on recurrence after operation; a less malignant or intermediate type; an almost or quite innocent type. The group of the gliomata supplies instances of each of these types. Among the malignant or rapidly increasing growths are some gliomas, fibroglioma, papilloma, pituitary and perhaps pineal. The comparatively innocent

type includes most endotheliomas, not a few gliomas, most of the fibromas, and the simple cysts.

Success in operation depends upon the nature and seat of the growth. If malignant, that is, of rapid growth, with tendency to recurrence, how far is it justifiable to attempt radical treatment? Tooth points out that the greater number of these neoplasms are gliomas, and so insidious is their growth, and so differently do individual brains seem to bear their expansion that only a distant and very often totally erroneous idea can be formed of what may be found at operation. As a rule, when the growth has given unmistakable evidence of its situation its complete removal is practically impossible, and, if incomplete, recurrence is inevitable. A temporary relief no doubt follows, and a prolongation of life for some months. Growths of a lower degree of malignancy, but of large size and ill-defined margins, have been removed and microscopically have presented characters of quiescence and almost innocence, but they have recurred in a highly malignant form. The opinion thus forces itself upon the observer that if left alone such a growth might have remained of the quiescent type for a much longer period if no more than a large craniotomy, or at the most a decompression had been done. Comparatively innocent non-infiltrating growths, not gliomas, offer every inducement for complete removal, in spite of a high mortality as judged by ordinary surgical standards. In the case of endothelioma, recurrence is so unusual as to be almost negligible. The treatment of simple cysts is so satisfactory, the result so permanent, and the disappointment so great on finding it post mortem, that the suspicion of it leads to much searching. But simple cyst is rare, only 1.9 per cent. The last of the comparatively innocent growths are the fibroma and perhaps the fibroglioma. The diagnosis of tumors in the extracerebellar region is so comparatively easy and accurate, and the surgical treatment at first sight so straightforward that the results as recorded by Tooth are disappointing in the extreme. The postoperative mortality is very high. As regards decompression, too, of the class of tumor in the extracerebellar region, the results are even worse than by the operative measures just mentioned.

On the whole, then, it may be said that brain operations are more dangerous than operations in any other part of the body. This, however, is only what might be expected, and considering the rapid progress that has been made in brain surgery during the past few years, it may be anticipated with some confidence that in time the high mortality rate following brain operations will be lessened considerably.

## THE PREVENTION OF TUBERCULOSIS IN NEW YORK CITY.

GREAT strides have been made in recent years in the direction of preventing tuberculosis in New York City. The ninth report of the Committee on the Prevention of Tuberculosis of the Charity Organization Society of the City of New York for the years 1911, 1912, and 1913 makes this fact very evident. The most important and far-reaching work of the committee has been its campaign to secure additional hospitals for tuberculosis. New York at the present time has 2,721 hospital beds for this class of patients, which while a great improvement on former conditions still are wholly inadequate. The records of the Health Department show some 40,000 known consumptives of whom the large majority live in tenement houses where they have neither the means nor facilities for proper care. Other valuable work inaugurated and carried on under the auspices of the committee includes work among school children, lectures, tuberculosis clinics, prevention of tuberculosis among Italians, and traveling exhibitions.

In large crowded centers of population as New York the problem of preventing the spread of tuberculosis is manifestly most important. A person afflicted with the disease is a source of constant menace to those living in his or her proximity, and may unless isolated be the means of disseminating the malady on a wide scale. Hence, the crying need of adequate hospital accommodation. It goes without saying that work among school children is a phase of the tuberculosis problem which must not be neglected and the educational side of the question is of utmost value. An early diagnosis and prompt treatment generally signify a cure, and it is only by teaching people how to recognize the symptoms of incipient pulmonary tuberculosis that early diagnosis and treatment are possible. The members of the Committee on the Prevention of Tuberculosis of the Charity Organization Society of the city have deserved well of the community, and their efforts to prevent the spread of tuberculosis should receive the aid of every citizen.

## THE EXCHANGE OF HOSPITAL ATTENDING PHYSICIANS AND SURGEONS

RECENT years have beheld a vast development in the idea of travel study in medicine and surgery. Clinical congresses and travel tours have demonstrated the advantage of the exchange of ideas and the dissemination of new methods. This development has not been confined to the medical sciences. It has been conspicuous in other branches, particularly in chemistry, mathematics, law, and the social sciences. The frequent calls made by the universities of Germany and Austria for professors in other institutions and the consequently frequent transformations of the faculties in these universities exemplify the desire to infuse new blood into the bodies of learned institutions. Science rebels against routine. Its healthy existence demands constant renewal. The German idea has found a new development in the creation of exchange professorships so that there now exist a series of exchange professorships between America on the one hand and Germany and France on the other. Would it not be feasible to apply this idea in hospital administration? One of the greatest drawbacks of the modern hospital system is the blighting effect of routine and institutionalism. However great may be the desire on the part of members of the hospital attending staffs to escape from the evils of working in a rut, however eager they may be by their attendance at national and international congresses to acquire new ideas and methods, however assiduous they may be in their visits

to the clinics of their colleagues both in their own country and abroad, nevertheless they cannot altogether escape the deadening influence of routine. The idea of an exchange system could be easily applied in any of the larger cities. It should occasion no revolution in hospital efficiency if two institutions agreed to exchange, for instance, one of their attending surgeons for a period of from three to six months or even longer. This does not imply that the exchange surgeons would at once or at any time try to upset the system that had been established in the institution to which they were assigned. It does not imply that they would seek to make any startling change in operating-room methods and technique. One would, on the other hand, conceive of the visiting surgeons both imbibing and imparting new ideas in a manner that is not obtrusive, influencing both the assistants and the other individuals connected with the hospital by the force of their example and the power of their personality. Whether the surgeons would care to make the exchange is another question.

### Verruga in the Human Subject Directly Traceable to Phlebotomus Verrucarum.

A case of verruga in man directly traceable to a species of Phlebotomus, *P verrucarum*, was reported by Charles H. Townsend from Chosica, Peru, in the *Entomological News*, January, 1914. An assistant of the writer was engaged in collecting specimen phlebotomus for the inoculation of laboratory animals and was bitten no fewer than fifty-five times by these insects. This occurred on September 17, and on October 1, on examination of the assistant's blood, verruga *x*-bodies were found in the red cells. At the time of writing, November 10, 1914, the patient was in the hospital in Callao. It should be said that on October 25 a decided rise of temperature occurred and the *x*-bodies were much increased in number, but the latest report stated that the temperature was lower than at first, and the case promised to be of a benign rather than of a malignant type. No eruption had appeared. Salvarsan was administered intravenously for the purpose of determining whether it would prove a specific against the disease, but apparently was of no avail.

## News of the Week.

**Medical Legislation.**—Gov. Glynn of New York recently signed the bill passed at the last session of the Legislature and known as the Boylan bill, which restricts the sale of cocaine and similar drugs. The bill prohibits the sale of such drugs except on the prescription of a reputable physician and provides that each package containing the drugs must carry a label or certificate with the name and address of the physician under whose prescription it is sold and the name of the person for whom the prescription was filled. All drug dealers and physicians will be supplied by the health authorities with official order blanks which must be used in making purchases of these drugs. In this way, it is hoped, track can be kept of all quantities of the drugs on sale in the city. For many years past, particularly in New York City, a relentless campaign against the promiscuous sale of these drugs has been carried on, and the passage of this bill, which goes into effect on July 1, will greatly benefit the work, making it easier to trace purveyors of the drugs and to convict illegal sellers after their arrest.

More than two thousand Christian Scientists from all sections of the State and some from neighboring States crowded into the Assembly Chamber at Albany on April 13 to attend the hearing held by Gov. Glynn on the McClelland bill, which makes legal the work of any person "who ministers to or treats the sick and suffering by mental or spiritual means without the use of any drug or material remedy." A number of prominent and apparently sane men spoke in favor of the bill, while it was opposed by many members of the medical profession. The Governor has not as yet announced his decision in the matter.

In New Jersey Gov. Fielder after a hearing on April 13, vetoed the bill passed by the Legislature which would permit the Rockefeller Institute to establish a research department in that State for the study of diseases of animals. The bill, which was an amendment to the present law for the prevention of cruelty to animals, was passed following the recent announcement that Mr. Rockefeller had contributed $1,000,000 for research work along these lines. Opposition to the bill was strongly voiced by the New Jersey Anti-Vivisection Society, and Gov. Fielder took the position that the bill as drawn was too broad in its scope since it would permit any body incorporated for the purpose under the laws of any State or country to conduct animal experimentation without any supervision whatever, and that while this right might safely be given to the Rockefeller Institute it would be unwise to confer it upon irresponsible persons who could obtain it merely by incorporating themselves.

In New York, again, Gov. Glynn has signed the bill designed to simplify the procedure necessary to the detention of weak-minded persons in State institutions. The bill authorizes any judge of a court of record to determine the mental condition of a suspected person on the application of a relative, friend, or probation, parole, or school officer, the application to be accompanied by a certificate signed by two physicians. The Governor has also approved the bill appropriating $5,000 for the expenses of a commission to investigate the care, custody, treatment, and training of the mentally deficient and to report on remedial legislation next year.

**The Philadelphia Vivisection Trial.**—After three days spent in taking testimony and forty-eight hours in deliberation, the jury in the case of Dr. Joshua E. Sweet, professor of surgery in the Medical Department of the University of Pennsylvania, failed to agree on a verdict and were discharged by the presiding judge. Dr. Sweet was indicted last year with five other members of the medical faculty of the university, all being charged with cruelty to animals in that the animals were neglected after having undergone operations. The evidence furnished by the prosecution came from the former keeper of the animal house and from women whom he had surreptitiously admitted to the house to inspect their quarters. It was charged that dogs which had been used for experiment were improperly fed, improperly treated, and improperly housed, and it was stated in support of the charge that the food given to the dogs was gathered from the waste at the University Hospital, that the wounds from the operations were not properly bandaged, and that the dogs were given only sawdust as beds. That the animals suf-

fered intense pain was the sworn testimony of one of the women, her observations having been made with the aid of an electric pocket flash light on night visits to the animal house. The defense introduced testimony to show that table scraps were the best food for the dogs, as providing variety, that healing of the animals' wounds was promoted by absence of bandages, and that sawdust was perfectly sufficient bedding, but was not allowed to testify as to the reason for performing any of the operations, nor to describe the benefits accruing from observation of the animals. In charging the jury the judge said in part: "To indicate a view on the part of these physicians that these operations upon dogs were made for scientific purposes to obtain information for the alleviation of human suffering, I charge you that the law of Pennsylvania does not allow pain and suffering, torment or torture to be inflicted upon dogs for any purpose except for the relief of the suffering of the dog itself. They have no right to torture the dogs or violate the law, as I have read it to you, for the purpose of obtaining scientific information. The law says that any person who is guilty of wanton and cruel torture of an animal shall be guilty of a crime. The law does not say they shall not be guilty if they do it for a scientific purpose. Scientific purpose does not excuse cruelty."

The judge defined torture as that amounting to more than ordinary pain and inconvenience, agony in itself, and wanton torture as that which is purposely inflicted. A cruel act was defined as a hard-hearted act, committed without regard to any suffering that it might cause. His charge was construed by the prosecution as a declaration that vivisection in itself is illegal, thus opening the way, in the opinion of many of those present at the trial, for the prosecution of all scientific men in Pennsylvania. The jury was reported to stand eleven to one, each side claiming the majority.

After the case had gone to the jury the university made public a report of a special committee of the Board of Trustees and a resolution of the full board approving the teaching work involving animal experimentation. The committee reported that the charges against the members of the medical faculty "were, as far as could be ascertained, absolutely without foundation," and said further that "all the great discoveries which have revolutionized medicine and surgery during the last fifty years have resulted directly from experiments on living animals, and could not have been attained in any other way. There can be no doubt that this work should be continued and encouraged in every possible way."

**Against Fraudulent Advertising.**—The Board of Aldermen of New York City recently passed a bill providing that anyone who publishes an advertisement containing assertions, representations, or statements which are untrue, deceptive, or misleading, shall be subject to a fine of not less than $25, or imprisonment for not less than five days or more than six months, or to both. In Chicago a similar ordinance has proved effective in a campaign directed against the venereal quack advertisers, and steps are being taken by the New York Department of Health to make the same use of the new law here.

**Reporting Infectious Diseases.**—The Department of Health of New York City has recently undertaken studies to determine whether the physicians in any one borough are negligent about reporting infectious diseases. In a recent issue of the *Bulletin* there is given the results of a study of case fatalities, which is instructive since a high case fatality may be due either to an unusually virulent type of disease or to the fact that fewer cases of the diseases are being reported. The following figures taken from the records for the year 1913 give the case fatality of five reportable diseases in the Borough of Queens as compared with the figures for the entire city:

| | NEW YORK CITY | | QUEENS | | CASE FATALITY | |
|---|---|---|---|---|---|---|
| | Cases | Deaths | Cases | Deaths | New York City | Queens |
| Diphtheria | 14,535 | 1,333 | 1,003 | 88 | 9.17 | 8.77 |
| Scarlet | 10,719 | 507 | 839 | 46 | 4.73 | 5.48 |
| Measles | 29,163 | 628 | 1,718 | 29 | 2.15 | 1.68 |
| Typhoid | 2,643 | 362 | 163 | 24 | 13.70 | 14.72 |
| Pulmonary tuberculosis | 22,671 | 8,601 | 980 | 419 | 37.94 | 42.93 |

It will be noticed that while the case fatalities in diphtheria, scarlet fever, measles, and typhoid fever, do not differ markedly in the two columns, in pulmonary tuberculosis the calculated case fatality is noticeably higher in the Borough of Queens, and as there is no reason for believing that the disease is more fatal in Queens than in the city at large, it is probable that there is some negligence in reporting tuberculosis in that borough. During 1913, as a matter of fact, eleven per cent. of the cases of pulmonary tuberculosis in Queens came to the attention of the Bureau of Records only at the time of death, not having previously been reported as cases.

**Surgeons Go Sightseeing.**—Immediately after the close of the International Congress of Surgeons last week a party of one hundred surgeons left New York for a short sightseeing trip. They will visit Philadelphia, Baltimore, Washington, Chicago, Rochester, Minn., Niagara Falls, Montreal, and Boston, returning to New York on April 28.

**Mt. Sinai Hospital.**—The annual report of Mt. Sinai Hospital, New York, shows that during the past year, 7,537 patients were treated in the hospital, 4,037 surgical operations were performed, and the dispensary consultations numbered 231,092. The expenditure for the year was $469,892, an excess of $48,507 over the receipts.

**Civil Service Examinations.**—The New York State Civil Service Commission will hold an examination on May 9, 1914, for the purpose of providing eligibles for the position of assistant physician in the State Homeopathic Hospitals at Middletown and Gowanda, at a salary of $1,200 a year, increasing $100 each to $1,600, and maintenance, including quarters, board, and laundry. The examination is open to both men and women, who are licensed practitioners in the State, graduates of a registered medical school, with one year's hospital experience or three years' experience in the practice of medicine. Unmarried men are preferred.

On the same day an examination open to women only will be held for the purpose of providing eligibles for the position of bacteriologist in the State Department of Health, at a salary of $1,200 per year. Applicants should have a thorough knowledge of the principles of bacteriology and

considerable practical experience in the bacteriological diagnosis of infectious diseases. A good general knowledge of clinical microscopy and of gross and histological pathology is also desirable.

Requests for application blanks for either of these examinations should be made to the State Civil Service Commission, Albany, N. Y., before April 28, 1914.

**Smallpox Warning.**—The New York City Department of Health, determined to prevent the spread of smallpox in the city, has issued an appeal to all citizens to be vaccinated promptly, and has warned employers that they are expected to see that their employees are vaccinated and that in the event of smallpox developing in any place of employment, such place will be put under strict quarantine. The department calls attention to the conditions existing in Toledo, O., where two hundred cases of the disease developed during December, January, and February last. Of the entire number of patients only one had been vaccinated, and in that case vaccination had been done thirty years before. The story of the Toledo epidemic is the story of hundreds of localized epidemics the world over. In New York City an epidemic of equal severity would mean 7,500 cases of the disease in three months, and would be a calamity to the people and bring ruin to the trade of the city.

**Personals.**—Dr. Gustave F. Ruediger announces his resignation as director of the State Public Health Laboratories and professor of bacteriology and pathology in the University of North Dakota, to accept the position of director of the Hygienic Institute and health commissioner for La Salle, Peru, and Oglesby, Ill., under an endowment by F. W. Matthiessen. Dr. Ruediger's address will be La Salle, Ill.

**Complimentary Dinner to the Congress Visitors.**—On Monday evening, April 13, a dinner was given by Dr. William Seaman Bainbridge, at the Hotel Biltmore in honor of Dr. E. Hertoghe of Antwerp, an authority on diseases resulting from disorders of the thyroid gland, of Dr. Alfred Jordan of London, the eminent radiologist, of Dr. Merrill Ricketts of Cincinnati, and of other distinguished European and American surgeons attending the International Congress of Surgery. About one hundred and ninety representatives of European and American surgery and medicine were present. After the usual speeches, Dr. Hertoghe, Dr. Jordan, and Dr. Ricketts gave addresses, illustrated on the screen, dealing with the subjects to which they are at present devoting special attention.

**Germ-Laden Milk Products.**—The National Commission of Milk Standards, which met in New York last week, condemned the present methods of manufacturing ice cream and recommended a crusade for a pure product. Examinations of ice cream in some two hundred stores, restaurants, and hotels in New York showed, it was stated, that the percentage of bacteria present varied from 1,000 to 21,000,000 per cubic centimeter. The worst ice cream is that sold in small stores on the East Side, while that furnished at big soda water fountains in the drug stores is also usually of poor quality. The butter supplied to New York was said to be of better quality than the ice cream, but here also there was room for improvement. The pasteurization of all milk before it was used for either ice cream or butter was recommended.

**Antityphoid Vaccination Advised.**—The New York Health Department has just issued through the daily press a warning to vacationists regarding the danger of contracting typhoid fever while in the country. The Bulletin of the Department states that the preparation of the typhoid vaccine has been so perfected within recent years that the number of marked reactions is small and antityphoid inoculations no wneed cause no more disturbance than the average smallpox vaccination. The department, therefore, strongly urges all physicians to advise patients who are about to go to the country to submit to this simple and effective protective measure. Antityphoid vaccine, prepared after the formula of the United States Army, can be obtained free from the Department of Health.

**Special Lectures at the New York Polyclinic.**—During the week of the meeting of the International Society of Surgery special lectures and clinics were given at the New York Polyclinic Medical School and Hospital. The first of these on Tuesday, April 14, was on internal photography as an aid to diagnosis and was given by Dr. Alfred C. Jordan, Medical Radiographer, Guy's Hospital, London. On Wednesday, April 15, Dr. E. Hertoghe of Antwerp, gave a lecture on hypothyroidism. Dr. Hertoghe illustrated his points by excellent stereopticon pictures of patients he had treated, before and after treatment. On April 16, Dr. Benjamin Merrill Ricketts of Cincinnati, gave a clinic and demonstration on the effects of wounds of the heart and pericardium. Dr. Ricketts reviewed the history of wounds of the heart and its immediate vicinity and drew from his own experience many illustrations of the manner and effect of such wounds. His lecture was pictured by lantern slides. On Thursday, April 17, Dr. Wyeth gave a lecture on the treatment of burns, Dr. John A. Bodine operated for the radical cure of hernia, Dr. Alexander Lyle lectured on the treatment of fractures and Dr. William Seaman Bainbridge on cancer.

**Laboratory Demonstrations.**—Dr. A. L. Soresi has invited the members of the Medical Society of the State of New York to visit his laboratory at 320 West 70th street, on April 29 and 30 and May 1 and 2, to witness a number of demonstrations of tissue and organ transplantation, blood transfusion, etc. The laboratory will be open from 9-11 A. M. and 2-6 P. M. on each day.

**Obituary Notes.**—Dr. FREDERIC L. H. WILLIS of Rochester, N. Y., a graduate of the New York Homeopathic Medical College and Hospital in 1865, and said to have been the original of Laurie in the novel, "Little Women," died at his home on April 12, aged 84 years.

Dr. MILES W. PALMER of New York, a graduate of the New York University Medical College in 1847, died at his home on April 10, aged 92 years.

Dr. ABEL B. APPLEGATE of Kosmosdale, Ky., a graduate of the University of Louisville, Medical Department, in 1874, died at his home on April 2, aged 63 years.

Dr. WILLIAM H. HAWLEY of Penn Yan, N. Y., a graduate of the Eclectic Medical College of the City of New York in 1851, died at his home on March 29, aged 89 years.

Dr. EARL P. WEAKS of Silver City, N. M., a graduate of the University of Louisville, Medical Department, in 1909, died at Paducah, Ky., after a long illness, from tuberculosis, on March 20, aged 29 years.

Dr. FRANKLIN J. SLOUGH of Allentown, Penn., a

graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1862, and a trustee of the Homeopathic State Hospital for the Insane at Ritersville, died at his home on April 3, aged 72 years.

Dr. Morris Parker Boyle of Glenside, Penn., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1898, formerly resident physician at the Children's Hospital of Philadelphia, and a member of the Medical Society of the State of Pennsylvania, the Montgomery County Medical Society, and the Philadelphia Pediatric Society, died at his home from appendicitis, on April 10, aged 38 years.

Dr. Francis S. Wilson of Jenkintown, Penn., a graduate of the Jefferson Medical College, Philadelphia, in 1870, and a member of the American Medical Association, the Medical Society of the State of Pennsylvania, and the Montgomery County Medical Society, having been at one time president of the latter, and formerly lazaretto physician at the port of Philadelphia, died at his home on April 7, aged 70 years.

## Correspondence.

### OUR LONDON LETTER.

(From our Regular Correspondent.)

MEDICAL RESEARCH—TROPICAL DISEASES—RADIUM—X-RAYS—INSTITUTE OF HYGIENE—LEPROSY—OBITUARY.

London, April 3, 1914.

The Local Government Board has authorized the following medical researches to be paid for out of the annual grant: (1) An investigation into causes of still births, (2) continuation of the inquiry into the cellular contents of milk, (3) continuation of the inquiry into the causes of premature arterial degeneration, (4) an investigation into the etiology of epidemic diarrhea in children.

Announcement of further investigations will be made at a later date.

The report of committee on the research fund for tropical diseases has appeared. There is again excess of expenditure over income, met, as before, by drawing on the accumulated balance of the fund. The need of more money is urged to enable work to be carried on in a number of directions now open. Reports from some colonies and protectorates are appended in response to the secretary of state's request for information on mosquito-borne disease. There are also reports of the work at the London and Liverpool schools of tropical medicine, and at several colonial laboratories; a report by the professor of protozoology of the London University, and another by Professor Nuttall on the work in the Quick Laboratory.

Radium still fills a large place in medical conversation, and in society proceedings. In my letter of March 13 I gave you an account of the discussion at the Medical Society of London. I will now add a brief notice of a lecture at the North London Society by Dr. Lazarus Barlow. He said finality was far off on a number of points, *e.g.* dosage. Apart from injurious action on animal cells, which is undoubted if used in too great strength, all cells are not equally affected by the same dose. Perhaps this might account for the different effects on different growths. The question whether radium acted like a thermocautery, or a strong acid, was treated in this way. There was some evidence that cancer cells, if subjected to radiation, short of their death, might become immunized. The work of Morson, Wedd, and Russ was quoted on this point.

If immunity could thus be produced it would most likely only be strictly specific for the individual; so the production of an anticancerous serum, such as was obtained in diphtheria, seemed most improbable. The lecturer insisted on histological examination, particularly the search for Altmann's granules in sarcoma. Then again he said the radium tubes must be periodically examined by a physicist to make sure that the radium was present to the degree that the surgeon believed. He considered radium should be tried, not only in distinctly inoperable cases, but also in some in which operation, though not impossible, was notoriously unsatisfactory—*e.g.* malignant neoplasms of the tonsil. But, on the other hand, he held that in cases in which surgery could show a good percentage of success, radium should not displace the knife at the present time, whatever might be the case in the future. On experimental grounds radium is contraindicated immediately after removal of a growth. Not so *x*-rays. No explanation can at present be given of this difference between *x*-rays and the closely allied gamma rays in this respect. In concluding, the lecturer said that when a growth had been absorbed after radium treatment the products of its disintegration must have been taken into the system at large, and he suggested that as long as such products remained uneliminated the patient would not be in a proper condition for surgical treatment. The use of *x*-rays in uterine myomata has made considerable progress, as in cases where other treatment has given no result, and hysterectomy seems to be the last resource, the reports encourage a hope that the operation may be avoided. Dr. Delpratt Harris addressed the Devon and Exeter Society on March 13, reading notes of four cases which were greatly improved, artificial menopause being established, with climacteric flushings and shrinking of the tumor. One patient, aged thirty-nine, treated in August, 1912, was able in the following May to go about her household duties, and felt quite well. Another, first treated in October, 1912, had slight hemorrhage in December, but none since, having had altogether five courses or cycles of treatment. A third case, aged forty-three, was equally successful. The menopause became complete in July, after three courses or cycles of treatment, the first in the previous September. The fourth case was of a woman of forty-nine, with a large fibroma occupying the position of a seven months' fetus. The treatment followed seems to have been Bordier's—a sitting every day or every other day for nine sittings—constituting a cycle. Omit twenty-one days, then give a second cycle. Sometimes four or five may be needed; very rarely six, for the effect seems cumulative, shrinking going on after discontinuance. The dose at a sitting is 1 or 2 millampères. At the first both uterus and tumor are treated; at the second, one ovary (right); at the third, the left; at the fourth, uterus and tumor again. In all the cases hemorrhage, which was prominent, ceased during the first cycle, and did not return, the appearance of the patient gradually improving.

Dr. F. A. Roper reported at the same meeting a case, widow of forty-nine, with rapidly increasing fibromyoma larger than a cricket ball, and pain at the periods severe, treated on the Hamburg system—series of five radiations through five points (two behind, three on abdomen), on successive

days, a fortnight's rest between each series, a filler of aluminum being used. A sitting was five to ten minutes, with current 3 to 6 milliampères. This patient had seven series. After one normal and two scanty periods, there was six months' amenorrhea, with complete relief of pain, shrinkage of sclerosis of the tumor to size of a tangerine orange.

Mr. A. C. Roper, as a surgeon, welcomed the method of diminishing the responsibility of operating on blanched patients. A number of questions were asked, and suggestions made, at this interesting meeting. One member proposed women of forty suffering from myomata, and blanched, should be treated with the rays, and later on have their tumors removed as a precaution against malignancy.

Mr. John Jackson, who has visited the chief settlements of lepers, including Molokai, the scene of Father Damien's labors, on Tuesday addressed a sympathetic audience in the Chapel Royal Savoy. He was introduced by the chaplain, who expressed deep interest he had taken in Damien's work, and remarked that in the precincts of the Savoy once stood the lazar house. Mr. Jackson said the work in India and the East was being now carried on at eighty-five stations. The organization was supporting, medically relieving, and evangelizing some 12,000 lepers and their children. Describing the terrible fate of Hindu lepers, he said they were cast out by their own kith and kin, and left to perish on the wayside. In India it was estimated that there must be now at least 250,000 lepers. By degrees the mission had extended their operations to China and Japan. In the latter there were 38,000 families in which leprosy was known to be present. The government had made some slight attempt to cope with the disease, or, at any rate, to try and relieve some of the sufferers, but that effort was only made within the last five years.

At the Institute of Hygiene, on Monday, Dr. Strickland Goodall roused the attention, and in many cases the wonder, of his audience, by a paper on "Heart Strain," in which he dwelt on the enormous work done by the heart in ordinary life. Beating at rates varying from 70 to 150, or more, he said at each beat it was calculated to do work equal to lifting a two-pound weight through one foot. To bring that home, he said, just put a two-pound weight in your palm, resting the elbow, and raise and lower the weight between the levels of the elbow and shoulder. When the heart was strained it lost some working power, especially that of meeting an extra demand. Acute strain was not easily produced in young, healthy adults, but if the seat of degeneration, it might occur in actions of everyday life, such as running to catch a train. Emotions affected the heart. Anger might increase its work from 152 to 224 foot-pounds per minute. The extra work continued some time after exertion. In one experiment, after a run, the work was increased to 360 foot-pounds. He said he has seen cases of rupture of the heart—one in which an animal actually died in this way through emotion. But the heart could do an enormous amount of extra work, as shown in an experiment of riding a bicycle up hill. The work as calculated in the case would have raised one and one-eighth tons through one foot. The work could also be economized by avoiding sudden exertion, running upstairs, and giving way to temper. Going to bed at 10 instead of 12, would save 876,000 foot-pounds per annum, reposing one-half an hour daily, 219,000 foot-pounds, and other calculations of the kind amused or surprised listeners. If the data could be obtained Dr. Goodall should calculate the extra tons lifted by the hearts of the crews of the boat race. On Saturday last that race seemed to absorb almost everyone's attention, even to the exclusion of the most exciting political crisis of the century.

The death took place on Saturday last of Mr. Bruce Clarke, M.B., Oxon, aged sixty-four, late senior surgeon to St. Bartholomew's Hospital, member of the council of the Royal College of Surgeons, examiner at Oxford University, and holder of other honors. His education was at Harrow and Oxford, when he took first class honors in natural science and the University Burdett-Coutts scholarship. In 1886 he received the Jacksonian prize for his essay on "Diseases of the Kidney Amenable to Direct Surgical Interference." He graduated in arts as well as medicine at Oxford.

## OUR PARIS LETTER.

(From Our Regular Correspondent.)

CHARLES RICHET—FRACTURE OF NECK OF FEMUR WITHOUT LOSS OF FUNCTIONAL POWER—TOXICITY OF ADENOMA OF THE PROSTATE—EOSINOPHILIA IN ADENOMA OF THE PROSTATE.

PARIS, February 15, 1914.

DR. CHARLES RICHET has just been elected by a vote of 42 to 10 a member of the Academy of Sciences. Nothing could be more deserving than this distinction conferred upon the winner of the Nobel prize for 1913. It is owing to the labors of Richet that serum therapy has attained such brilliant results. As early as 1887 he showed the therapeutic value of the blood serum of vaccinated animals. Since then he has explained the phenomena of anaphylaxis and he has shown that serum sickness is a manifestation of anaphylaxis. The Academy of Sciences has honored itself in drawing Charles Richet to its bosom.

"Fractures of the Neck of the Femur without Loss of Functional Power" was the subject which was discussed at the Surgical Society on December 3, 1913. M. Auvray reported a case in which the patient had had for three years an intracapsular fracture of the neck of the femur, as evidenced both clinically and by means of the *x*-rays. There was neither immediate nor remote loss of functional power. The traumatism caused only certain pains about the hip and a slight limping. On December 10, 1913, Delbet after an examination of the radiographs doubted whether there was a fracture. He believed, moreover, that walking would be impossible after a fracture of the neck of the femur. This opinion was shared in by Broca, Demoulin, Savariaud, and Ombredanne. On the other hand Kirmisson declared that it was possible, at least in the child, to observe cases of fracture or cases of separation of the superior epiphysis of the femur, lesions verified by the *x*-rays, which did not prevent walking. Likewise, Chaput has observed a case of fracture in which walking was possible. On December 17, 1913, Savariaud contested the interpretation given by Kirmisson in the cases observed by the latter. These cases he believed were really instances of spontaneous coxa vara in which the traumatism had played only an insignificant rôle. Broca concurred in this opinion. The discussion on the same subject was resumed at the meeting of December 24. Kirmisson in support of his thesis reported the observation made by Moidret of Mans,

according to whom the standing posture was possible in spite of an epiphyseal separation which was clinically well marked and which was demonstrated by *x*-ray examination. Hartmann has observed in a boy 15 years old the same separation of the epiphysis and besides the boy was able to return home unaided on foot. Auvray alluded to a number of cases of the same nature which he has seen reported in the literature. From this long discussion one may conclude that the diagnosis of fracture of the neck of the femur was often unrecognized before the days of radiography. Many cases were regarded as instances of contusion of the hip joint. It is therefore of great importance in extraarticular traumatism of the hip to practise radiography, for otherwise a fracture may be overlooked and a chronic arthritis or a secondary deformity of the hip may result.

Recalling the experiments already made by Thaon upon the toxicity of the prostate, Leguieu and Gaillardot of the College of France have injected into dogs a maceration of an adenoma of the prostate. They have thereby produced a marked hypotension of the blood which appeared immediately. This hypotension caused the death of several animals when the dose employed was from 0.50 gram to 1 gram of the extract per kilogram of body weight. Leguieu concluded from his experiments that a number of so-called prostatic accidents are due to the toxic action of the adenomatous tissue and not to mechanical interference with micturition. The examination of the blood of prostatics has confirmed this opinion. Thus, Morel and Chabanier studied the blood of individuals suffering from prostatic adenoma and detected an eosinophilia varying from 4 to 10 per cent. or more. On the date following the removal of the adenoma this eosinophilia fell rapidly to the normal figure of 1 to 2 per cent. Moreover, the examination of the blood in the tumor also revealed a considerable degree of local eosinophilia. Adenoma therefore appears to be a focus of eosinophilia and toxicity. Although there is no ratio between the size of the adenoma and the degree of its toxicity, these laboratory studies enable one to draw the following practical conclusions: (1) The examination of the blood in doubtful cases provides a diagnostic aid of value in adenoma and cancer of the prostate, eosinophilia not being present in cancer. (2) The demonstration of eosinophilia associated with habitual prostatic symptoms without an increase in the size of the prostate enables one to conclude that a small adenoma is present and that it is at the same time markedly toxic. Guyon refers to those prostatics in whom there is no enlarged prostate. (3) In these cases and even in cases of the absence of a clinically demonstrable hypertrophy, Freyer's operation, in enabling one to enucleate at times an adenoma that is very small will cause the untoward symptoms to disappear.

## THE PLAGUE IN HAVANA

(From Our Regular Correspondent.)

HAVANA, April 14, 1914.

ALTHOUGH since the middle of March there had been a few cases of bubonic plague in this city, the outbreak had really no great importance, as the radical disinfections and other measures established by the health authorities appeared to be amply sufficient to cope with the disease. But in the past few days, more cases have appeared and although all the cases have occurred in the "infected zone" the outbreak has taken a more serious character. In all, seven cases have occurred, and of these two have died. All cases have occurred in Spaniards, living in large and insanitary warehouses. One patient has been discharged, two are on the road to recovery; the last three have been diagnosed only in the past three days and are being treated with Yersin's serum, like the others. Fortunately the pneumonic form of the disease has occurred only in one of the two fatal cases. The number of the cases and the fact that all have occurred in the business district of the city give some importance to the outbreak.

Repeated fumigations of the places where the patients came from are to be followed by the complete closing of seventeen city blocks, and over 9,000 inmates have been obliged to leave their household belongings as well as all personal effects in their houses. All persons in need will be provided for at the Government quarantine stations, after being bathed and thoroughly disinfected. The quarantined district includes seventeen city blocks and soldiers are patrolling the streets with strict orders not to allow anybody in that section.

The closed buildings are to be kept so for twenty days. Drs. Nuñez, Guiteras, and Lopez del Valle, chief sanitary officers, as well as the Board of Infectious Diseases, composed of Drs. Agramonte, Bango, Albertini, Martini, Guiteras, and Chaumont, are doing an immense amount of good work, instituting strong and necessary measures that are obeyed by many willingly, but by others only under the compulsion of the police.

**1. Gonorrheal Metastatic Arthritis.**—H. W. E. Walther points out that Hahn of Breslau, who has made an exhaustive study of this disease, states that of the numerous metastases of gonorrhea which he has met with in his vast experience, gonorrheal rheumatism deserves first place. It has been reported from conservative workers that between two and three per cent. of all patients suffering from Neisserian urethritis become afflicted with this disease. The malady is more common in men than in women. It has been found that the condition may be due to constitutional invasion and localization in the synovial membranes of joints, tendons, and bursæ by the gonococcus alone, and sometimes apparently to mixed infection with pyogenic bacteria in addition. The types of this affection come under the following five headings: (1) Arthralgia without definite lesions in the joint. (2) Acute serous synovitis with much periarticular swelling. (3) Acute fibrinous or plastic synovitis with slight effusion. (4) Chronic serous or purulent synovitis. (5) Involvement of periarticular structures, such as bursæ and tendon sheaths.

**2. Seasonal and Meteorological Influence on Tuberculosis.**—N. R. Burns notes that barometer change seems to have very little effect upon the symptomatology of tuberculosis. In a few instances hemorrhages have occurred following a fall in the barometer, but in

an insufficient number of instances to indicate a constant relationship. This is probably a matter of coincidence only in so far as barometric changes are concerned. There are a larger number of patients having blood-streaked sputum in March, May, and especially in June, than in other months. Hemorrhage occurred more frequently in June than in any other month. A relative humidity of high degree coincides with increased cough and chest discomfort, an increased number of vesperal fevers, and an increased number of bed patients. Following weather relaxation and change from a protracted period of low glass reading wet and dry, together with high barometer, there seemed in several instances to be small epidemics of streaked sputum and occasional hemorrhages. For seven different days in June the number of vesperal fevers rose to sixty-five and over, which was in excessive amount. Some reactions are not accompanied by humid weather. A plausible explanation is suggested in the fact that on several of these days visitors in large numbers, frequently over one hundred a day, were visiting the patients, stirring them with family and other troubles.

**2. Internal Pachymeningitis in Young Children.**—A. Gordon reports two cases of this condition which presented the following common symptoms: Convulsive seizures, elevated temperature, hypertonicity of the musculature, rigidity of the neck and dorsum, a profound mental hebetude, finally the absence of microorganisms in the cerebrospinal fluid, which at all times remained clear and transparent and which was under very high pressure. There was hemorrhage into the retina in the first case, but not in the second. In both cases internal pachymeningitis was present, but in the first case there was also a hemorrhage. Apart from the state of the cerebrospinal fluid, all the other symptoms may be also those of meningitis of all varieties. In an attempt to find some phenomenon which during life could be considered pathognomonic or at least indicative of internal pachymeningitis, hemorrhagic or non-hemorrhagic, one's attention must naturally be directed toward the condition of the cerebrospinal fluid. Blood may be found in this fluid, not only in the disease in question, but also in cases of hemorrhages occurring in the substance of the brain tissue. The peculiar persistence of transparency and clearness of the fluid, and particularly the total absence of microorganisms by direct examination and by culture methods, are the special phenomena on which a diagnosis of pachymeningitis perhaps can rest. The presence of blood alongside of the pachymeningitis may perhaps be determined from the retinal hemorrhages, which have been found by the majority of observers in adults and in children. It is evident that all the other symptoms must be taken into consideration, but if in addition the foregoing conditions of the cerebrospinal fluid are found, the presumption is in favor of internal pachymeningitis. The early detection of this form of meningitis will lead to early intervention, either by frequent lumbar punctures, which gave considerable relief to the author's first patient, or by more radical operations of which Haynes's drainage of the cisterna magna appeals most strongly.

**3. Rammstedt's Operation in Hypertrophic Pyloric Stenosis.**—H. Lilienthal states that Rammstedt has reported two cases operated upon by his method with recovery. He makes a longitudinal incision through the indurated tissue down to the mucosa, but not through it. There is an immediate separation of the divided structures and the pylorus at once becomes patent. Without visceral suture or plastic of any kind the abdomen is completely closed. The operation is short and easy. The wound of entrance through the abdominal wall need not be large. The handling of the viscera is minimal. The contrast to the delicate and difficult posterior gastroenterostomy, with its accompanying evisceration and handling of the parts is striking, and perhaps most important of all, Rammstedt's operation, preserves the normal relations of the gastrointestinal tract. This preservation is obviously impossible in gastroenterostomy.

**4. Toxemias in the Genesis of Hyperthyroidism and Their Treatment.**—C. E. de M. Sajous points out that a great variety of poisons are capable of causing goiter, or, in other words, of evoking a sufficiently violent and prolonged hyperthyroidism as to cause hyperplasia of the gland. This result coincides with the pathogenesis of exophthalmic goiter. Among its causes are: Infections, including tonsillitis, acute rheumatism, typhoid fever, tuberculosis, influenza, and syphilis; an excess of intermediate waste products such as those of autointoxication; the menopause, physiological or postoperative; pregnancy and parturition. Indeed, were one to trace back to their original source many cases of the disease, one would probably find that all toxic substances capable of causing goiter can also evoke exophthalmic goiter. This would account for the relative frequency of the latter disease in goitrous districts where water-borne toxic substances, organic or inorganic, are known to be the pathogenic agents. Beginning with measures that are capable of opposing the intoxication in goiter, it is known that when a patient is removed sufficiently early from a goitrous district, or supplied with water from a nongoitrous district recovery is apt to occur. Intestinal antiseptics will also prove effective where a pathogenic organism in the alimentary canal is the cause of the struma. McCarrison, for example, found that thymol, in 10-grain doses three times a day, is either curative or highly beneficial in sixty-eight out of the eighty-two cases the final result of which he was able to trace. Exophthalmic goiter shows a corresponding list of measures calculated to oppose autointoxication. Kocher found sodium phosphate effective, a result he ascribes to its action on the intestines. Epstein, in fact, has shown that coprostasis was a frequent accompaniment of the disease. W. H. Thomson banishes all meats and administers intestinal antiseptics. In addition to washing out the colon frequently or giving purgatives, Solomon Solis-Cohen administers the salicylic compounds, betanaphtol, benzonaphthol, hexamethylenamine or guaiacol carbonate. Menthol was found very beneficial. These and other intestinal antiseptics have been used by various authors. Here, again, the source of intoxication is controlled and the thyroid apparatus as a defensive mechanism is stimulated to a correspondingly less degree. The author urges: (1) that much light would be thrown on the pathogenesis of goiter and exophthalmic goiter if the antitoxic and bactericidal functions of the thyroparathyroid apparatus were taken into account; (2) that the best results are attained in the treatment of these two disorders when a toxemia due to any one or more of many endogenous or exogenous factors is regarded as the cause of goiter and also of exophthalmic goiter when this condition is not due to violent emotions, shock, and kindred agencies; (3) that inas-

much as any case of goiter may become one of exophthalmic goiter, the appearance of any enlargement of the thyroid not ascribable to an ephemeral cause, pregnancy, an acute febrile process, etc., should at once indicate that the patient be placed under a treatment having for its purpose the elimination of the toxemia and its cause. As to the relations of the question to pathology, the author believes (4) that while a goiter is the result of exaggerated functional activity of a defective gland, exophthalmic goiter is the result of a functional normal gland which, as such, is able to produce an excess of secretion sufficient to cause a thyrotoxicosis.

7. **The "Why" of Obesity.**—F. McKelvey Bell states that it is apparent that any disease, surgical operation, or natural decay which destroys the ovary or testicle disturbs the normal balance between fat and lean. In addition any excessive loss of ovarian or testicular secretion tends in a lesser degree to the same end. It follows as a natural inference that some secretion from these glands increases oxidation, stimulates cellular function, and thus has a powerful influence in preserving the normal body weight. In fact, the author suggests that, without being too iconoclastic, one may go a step farther. If it be remembered that azoospermia occurs commonly in the very obese, and that in pregnant women, who for the time being are deprived of the advantages of ovulation, the subcutaneous fat increases so markedly; it is not unreasonable to suppose that the normal body weight is not preserved so much by the glands proper as by their products, viz., the corpora lutea and the seminal fluid. According to W. E. Dixon the composition of orchitic extract of all animals is practically identical; this substance contains a toxic nucleoalbumin which causes cardiac inhibition, and an important part, spermin, found in the semen, which causes congestion of the abdominal viscera, ovaries, and testicles. The author suggests the name asexual obesity for this form.

1. **Respiratory Experiments on Man.**—Y. Henderson states that clinicians are beginning to realize that the alveolar carbon dioxide is a normal constant, equal in clinical importance to arterial pressure and its determination is almost as easy and as readily applicable to clinical conditions. Up to the present, however, respiratory experiments have been little employed on man in physiological laboratory courses. In cardiorenal and diabetic cases, as well as in normal patients at great altitudes, the alveolar carbon dioxide is the index of the degree of acidosis.

2. **Cardiac Effects of Immoderate College Athletics.**—L. Shumacker and W. S. Middleton conclude that athletic training leads at first to physiological hypertrophy of the heart; but when prolonged and marked by severer athletic contests it usually leads to hypertrophy plus dilatation of a variable degree frequently marked by valvular insufficiency. Functionally, the hypertrophied heart, even when dilated and giving distinct evidence of valvular insufficiency, may prove more fitted to carry the man through a severe athletic contest than a normal heart would be. On the other hand, acute cardiac dilatation occurs more frequently in athletes and men used to severe muscular strain than in normal men, and the ultimate effects are more prolonged and severe. There is reason to believe that for normal human activities an "athletic" heart is distinctly disadvantageous.

3. **Ischemic Pains.**—A. R. Mitchell states that this object may be considered from two viewpoints. Is the cause of the positive signs and symptoms dependent on some irritant which acts on some part of the sympathetic nervous system, causing a circumscribed spasticity of the vessels under its control, or is it due to some change in the part involved? To the author it appears most probable that both conditions may be and later on are present in all cases. In the most typical of all ischemic pains, angina pectoris, we have added a third condition which may also be present in all cases to a varying degree, namely a general rise in blood-pressure; whatever the cause, the objective and the subjective phenomena are the same: a lowering of the blood supply to the part, because of the reduction of the blood supply, and pain, which in this condition is the call for oxygen, either from the musculature or from the nerves themselves, or from both. The pain in an inflamed nerve is most likely due to want of oxidation under conditions of infection. It is more than probable that some of these circumscribed ischemias have their origin in the part affected, as in the leg cramps of overexertion from walking, and the pain in the chest from mountain climbing, in which the muscle hunger is made more noticeable by a lesser supply of oxygen. The cramps of the swimmer are probably a circumscribed ischemia, made more certain by the reduced surface temperature. But are these manifest symptoms due wholly to reflex impulses through the centers, to some special internal secretion of the cells involved, or to an altered hormone? Here one enters a field which, although much explored, has brought but little information.

4. **Etiology of Arthritis Deformans.**—E. C. Rosenow notes that the common presence of foci of infection, the history of previous infections, the occasional isolation of bacteria from the joints in chronic arthritis, and the fixation of complement by certain bacteria in arthritis deformans (Hastings) suggest strongly the infectious character of this disease. The similarity, on the other hand, of the articular changes with those found in the nervous arthropathies; the associated dystrophies of the muscles, skin and nails; the symmetrical onset, the frequent involvement of nerve-trunks; and the exacerbations following nervous shocks are commonly cited as indicating a neural origin. The chief objections to the infectious theory of arthritis deformans are that so many cases do not give a typical picture of infection and that no one thus far has isolated any organism from the tissues or joints in a considerable number of consecutive cases. Bacteriological examination of the blood and of the articular exudate, when obtainable, usually has given negative results. It occurred to the author that the lymph-glands draining the involved joints would be a good place to look for organisms, and

this has been done in a considerable number of cases. The glands are excised with strict aseptic precautions under local anesthesia, and cultures are made at once, a portion of the gland being reserved for microscopic study. The part used for cultures is dipped into boiling water or passed through a Bunsen flame so as to sterilize the surface rapidly; it is cooled in sterile salt solution, it is emulsified in a specially devised sterile air chamber, and inoculations made chiefly into tall columns of ascites-dextrose-agar. In this way organisms have been isolated from the glands in all but three of thirty-eight cases of arthritis deformans, the duration of the disease ranging from two to seventeen years. Streptococci have been obtained in fourteen cases; a peculiar streptococcus-like organism at first completely or partially anaerobic, in nine cases; the *Bacillus welchii* in nine cases; staphylococci in three; *B. mucosus* in one case; and the gonococcus in one case. In a number of glands several organisms have been found at the same time. In no instance have the streptococci been hemolytic for human blood. They resemble on isolation the usual *Streptococcus viridans* more than hemolytic streptococci, although only three strains produced green on blood-agar plates. There is often a marked difference between the type of organisms found in foci of infection such as the tonsil, and the type of those found in the glands (or joints). All the streptococcal forms isolated have shown a marked preference for anaerobic conditions of growth in the primary culture.

7. **Gas Bacillus Infection.**—A. H. Baugher recommends the use of blood-cultures as the method of diagnosis of this condition. Welch and Nuttall have observed and called attention to the fact that the gas bacillus is often present in the blood stream, as shown by necropsy. So far as Baugher has been able to find, no previous cases of recovery after its detection in the blood stream during life have been so far put on record. He reports here, however, a series of four cases with three recoveries and also briefly reviews the case reports in which positive cultures have been obtained. Each blood culture in these cases was made from about 10 c.c. of blood divided about equally into two flasks each containing about 50 c.c. of broth. Both plain and glucose broth were used and in two cases the growth occurred only in the latter. The cultures obtained were pure except in one case where the *B. mucosus capsulatus* was an associated organism. The bacillus was also identified by injecting the blood culture into rabbits and identifying it in their organs. The author calls attention to the wide distribution of this germ and the possibility of the diagnosis and cure of gas bacillus infection by proper surgical treatment.

9. **Sporotrichosis of the Eye.**—W. H. Wilder and C. P. McCullough report a case of this condition. They also review other cases reported in the literature and discuss the special points of diagnosis from syphilis, tuberculosis of the conjunctiva, and Parinaud's conjunctivitis. The presence of the organism or one closely resembling it should suggest sporotrichosis, though it is possible that cases of it have been mistaken for Parinaud's conjunctivitis.

13. **Vaccine Anaphylaxis.**—R. Wallace reports an unusual case of this condition in a woman aged 53, who had been treated for furunculosis three years before and effectively cured by four doses of antistreptococcic vaccine. The patient asked for a repetition of the treatment for boils from which she was suffering at the time seen, and an injection of fresh stock vaccine, containing 100,000,000 streptococci, 400,000,000 staphylococci, and 200,000,000 colon bacilli was given. There was only a slight local reaction and considerable improvement followed. On the eighth day a double dose of the same was administered and within a few hours a scarlatinal rash appeared which finally involved the entire body without, however, producing any constitutional disturbance. The condition was not an exanthematous disease nor was the eruption related o parenteral protein digestion. The condition was treated by catharsis and alkalies and the eruption gradually faded away, but was so intense and indurated that it left considerable fissuring of the skin in the flexures and a mild desquamation in many parts.

6. A Case of Thoracic Aneurysm of Unusual Size. G. Cooper
7. Extrathoracic Aneurysm of the Transverse Arch of the Aorta. D. W. Keiller.

2. **Physiology and Pathology of Uterine Hemorrhage.**—H. B. Whitehouse states that the essential machinery involved in the production of uterine hemorrhage suggests that excessive bleeding may arise from: (1) factors in relation with the endometrium and (2) factors associated with the endocrinous glands, especially the ovary. To these two primary groups the author would add a third—viz., factors concerned in the abnormal production of pelvic venous stasis. It appears probable that under Group 1 are included many cases of so-called menarrhagia, while Groups 2 and 3 are more closely related to metrorrhagia or intermenstrual bleeding. At the same time these groups undoubtedly overlap with the production of irregular hemorrhage, so that it is not possible to draw any hard-and-fast line. The author in discussing the value of curettage in the therapeutics of uterine hemorrhage states that its use is principally for diagnostic purposes. If the examination of the curetted endometrium is taken in conjunction with an analysis of the menstrual discharge, and care is taken to correlate the appearances of the endometrium with the period of the sexual cycle, much valuable information may be gained as to the cause of a specific hemorrhage. Curettage at the two extremes of sexual life is a useless procedure except for diagnostic purposes. It is not possible to alter the character of the endometrium by any amount of curetting. This is proved by the examination of repeated curettings from the same uterus. In glandular hyperplasia of the endometrium curettage is only of temporary benefit. Treatment of uterine hemorrhage to be successful must be based upon a physiological basis. Thus, where hemorrhage is due to the absence of thrombokinase, such as occurs in menorrhagia due to the atrophy of old age, attempts may be made to replace the same. In the case of puberty natural cure usually takes place within a few months by development of the endometrium, and in the great majority of patients there is no necessity for local treatment. At the menopause, however, if hemorrhage is very profuse or prolonged, the application of thrombokinase in the form of an extract of the endometrium or an extract of testicle is useful in immediately controlling the same. Fibrin ferment directly applied to the endometrium is also of service in directly checking hemorrhages of this nature. If bleeding is due to excessive thrombolysis, the result of hyperplasia of the endometrium, temporary relief may be obtained by curetting. If bleeding recurs partial oophorectomy should

be performed. This procedure has answered admirably in those cases that have come under the author's notice in which profuse losses are associated with a high thrombolytic power and an extreme hypertrophy of the endometrium. If hemorrhage appears to be the result of venous stasis appropriate means must be taken to relieve the same, either by purgation in the case of portal congestion or by operation when the condition is severe and chronic inflammation is present. In those cases in which the uterus has lost its power of regulating the supply of blood to the endometrium, as in fibrosis or arteriosclerosis, hysterectomy appears to be the safest and best method of treatment.

3. Some Causes of Failure of Vaccine Therapy.—W. M. Crofton states that most cases of failure in this treatment are due to want of proper application of the method to the patient. There are several potential causes of failure to be taken into consideration: (1) Failure of patient to react; (2) failure to diagnose the infecting microbes; (3) incomplete immunization and (4) failure to give the doses at proper intervals. It is of course essential, in order that vaccine therapy should be successful, that the patient's tissues should be capable of responding to a further stimulus. One finds that old people react badly and so the initial dose must generally be smaller, and one cannot as a rule increase the dose to the extent that is generally possible in younger people. Diabetics are extremely sensitive, and the doses given must be small. Acidosis, chronic nephritis, and cachexia are conditions in which a poor response may be expected. One cannot tell in any given case the size of the dose that must be attained before success is achieved. The fourth and last cause of failure is the giving of the vaccine at fixed intervals without regard to any reaction the patient may have had.

5. Diagnosis of Pulmonary Tuberculosis by the X-Rays.—A. C. Jordan points out that the rational diagnosis of early pulmonary tuberculosis has been kept back many years by the teaching, founded on stethoscope observation, that the disease commences at the apex. *X*-ray observations have made the fact increasingly obvious that this is not the case; it is quite rare to find tuberculous mottling limited to an apex, and when there is apical mottling there is nearly always mottling in the lung between the root and the apex, and also mottling disposed radially from the root along the air tubes toward the periphery. The usual mode of invasion of the lungs is as follows: The first change is a catarrh of the large air tubes; the lumen of the tubes fills with epithelioid cells. The catarrh may extend to the small tubes, and there may be sputum in which a few tubercle bacilli may be found by studious search. Up to this stage there are no *x*-ray changes in the lungs; the disease is practically a bronchitis. The next stage, however, is the most important of all; tubercle bacilli, accompanied by other microbes, as a rule, pass through the walls of the air tubes, and lead to the appearance of groups of leucocytes in the connective tissue surrounding the bronchial cartilages. This peribronchial infiltration is readily visible with the *x*-rays, it gives rise to the fine mottling which is characteristic of early tuberculous disease of the lungs. The distribution of this mottling is always a radial one from the root, though from the first the mottling may radiate out to the periphery of the lung and up the level of the clavicle. The distinctive feature of the mottling is its peribronchial arrangement along the branching system of air tubes. While this mottling is appearing the glands at the root are fulfilling their normal function; the root shadows increase the size. This condition the author has named "peribronchial phthisis"; undoubtedly it is the usual mode of onset of pulmonary tuberculosis. Under suitable conditions a cure may occur, the leucocytes disappearing and their place being taken by new fibrous tissue. On *x*-ray examination there would then be no mottling but an increase in the thickness of the radiating lines around the air tubes. In unfavorable cases the leucocytic invasion of the tissues goes on, the individual mottles coalesce to form blotches, the disease reaches the apex (by way of the air tubes) and soon gets a firm hold in this, the most vulnerable region of the lungs. The physician relying on his stethoscope to inform him as to the extent of the disease, can detect no signs (except perhaps those due to bronchial catarrh) until the infiltration is approaching the apex; early peribronchial phthisis gives no physical sign of its presence. By this time the disease is well advanced, and the most favorable early stages have slipped by.

1. Lister: The Laboratory and the Bedside. R. H. Russell.
2. Remarks on Infection by *B. coli* in the Puerperium, and on the Infective Condition of Pregnancy. H. J. F. Simson and J. M. Bernstein.
3. Plague in Ceylon. A. Castellani and M. Philip.
4. An Instrument for the Detection of Slight Degrees of Nasal Obstruction. H. A. Kisch.
5. A Case of Temporosphenoidal Abscess in the Course of Chronic Otitis Media. A. Ryland.
6. Two Cases of Ocular Disease Associated with Pyorrhœa Alveolaris. S. G. Tibbles.
7. The Milroy Lectures on the Hygienic Aspect of the Coal-mining Industry in the United Kingdom. F. Shufflebotham.

2. Infection by B. Coli in the Puerperium.—H. J. F. Simson and J. M. Bernstein state that the possibility of autogenous infection is now well recognized. Bacteria which normally inhabit certain parts of the body as saprophytes can, under favorable conditions of environment, acquire virulent characters, so that one finds the streptococcus or the *B. coli* or the *B. pyocyaneus* (a less frequent inhabitant of the alimentary tract) at times settling down on a diseased endocardium or kidney or other part of the urinary tract and initiating pathological processes. It may be granted that the organisms are constantly entering the blood stream in some numbers, but under ordinary conditions of health are easily overcome by the defensive agents. But sometimes these bacteria may settle down to a saprophytic existence in parts of the body usually free from them, so that it is possible for the *B. coli* to live in the female bladder for long periods without producing any disturbance. Where there exists disease of the bladder or the kidneys the manifestations are fever of indefinite duration, often rigors, and invariably the urine is of high acidity, containing pus and swarming with bacilli. The urine is so acid as to produce scalding in passage. Though the pyrexia may continue for some time, the patient does not manifest general symptoms of such severity as are met with in septicemia; nor can microorganisms be found in the blood stream by cultural methods. The condition is one of toxemia. There is but slight leucocytosis, though in more extensive disease of the kidneys, where abscess formation is advanced, this may be more marked. The results of treatment may be summarized under three groups: (1) Cure may result and the bacilli disappear from the urinary tract; (2) the symptoms may be relieved and the bacilli disappear so long as the patient is kept under treatment, but it will be necessary to give prophylactic doses of vaccines at increasing intervals of time; or (3) the condition may subside and the bacteria continue to inhabit the bladder as harmless saprophytes. The result of vaccine treatment is as a rule, rapid, and even after the first dose the temperature may even fall and the toxic symptoms be relieved, while the bacteria

may disappear from the urine. But even so, one must be guarded in giving a prognosis of rapid return to health or in discontinuing the treatment too soon; for, though it is easy to control the bacterial activity, in some cases it is difficult and occasionally impossible to entirely inhibit them. Consequently the vaccines should be continued in increasing doses at increasing intervals of time for several weeks and the further treatment should be controlled by periodical examinations of the urine.

**4. An Instrument for the Detection of Slight Degrees of Nasal Obstruction.**—H. A. Kisch has designed an instrument which he calls the rhinomanometer. The objects kept in view have been that the instrument should demonstrate both inspiratory and expiratory obstruction, should be easy to use both by the patient and surgeon, should not involve waste of time, and should not be expensive. It consists of a large straight glass tube of narrow bore, the distal end of which is finely constricted. To the proximal end is attached a rubber tube ending in a broad nose piece. The glass tube is about nine inches long, and graduated into arbitrary divisions. A cylindrical glass vessel is required in which water is placed. The tube is immersed until the water in the tube and outside are brought to the same level. The nosepiece is pressed close to one nostril; the other is closed by the thumb pressed upwards from below—not by pressing the ala against the septum. The patient then with his mouth wide open sees how much water he can breathe in and out of the tube in five seconds, breathing as hard as he can. The same procedure is followed with the other nostril. The result gives a comparison of the two nostrils with each other, and with an average person. The average individual can breathe in and out of the instrument five divisions, but from four to six are within the normal range. Anything below four indicates definite obstruction. The results do not indicate any scientific measurement but determine the presence of obstruction in a quick and easy way. Seeing that the nosepiece must alter the shape of the vestibule to a certain extent, it must be determined beforehand by inspection whether obstruction is present here. For example, collapsed alæ or a dislocated columnar cartilage might be the cause of the obstruction. If the instrument gives a normal reading, then the whole obstruction is due to the anterior condition, but if otherwise there must be some posterior obstruction as well. As far as the author can determine an obstruction showing lack of inspiratory power of more than three degrees is not curable by simple measures, but demands operative treatment.

**Treatment of Syphilis.**—Blaschke, writing upon certain fundamental questions of the therapy of syphilis, states that his former sceptical attitude in regard to a special spirochete which attacks the nervous system has undergone a change. He now looks upon such a microorganism as a possibility. A potent reason is the great frequency of conjugal and familial tabes and paresis, as well as of group infections where a common virus has been active in producing these last-named diseases. It is said that the latter cases, like those of ordinary syphilis, respond to a vigorous initial treatment. This we are unable to discuss because we have had the Wassermann reaction but 6 years, while paresis usually appears between 11 and 15 years after infection, and tabes still later.

**The Breslau Epidemic of Erythema Infectiosum.**—Tobler states that last November a child appeared at the clinic with a peculiar exanthem, which bore some resemblance to several of the well-known forms. The dermatologists pronounced it an erythema toxicum. Not much was thought of the case until another exactly resembling it entered the clinic. It was then recalled that an "erythema infectiosum" had been described some years ago as a new disease. Descriptions can be found as far back as 1886. Some reporters mentioned the close resemblance to German measles. In 1899 Escherich and his pupil Schmidt gave the first description of the disease as an entity, while Sticker named it eryhema infectiosum. Some 300 cases are now upon record. Numerous attempts have been made to change its name, but none of these substitutes possess any advantage over that now in use. Evidently the English would term it "the fifth disease" with reference to Duke's "fourth disease." The condition is thoroughly harmless.

**Treatment of Pernicious Anemia by Splenectomy.**—Porr refers to the very brief history of this subject, all the literature dating from last year. Naturally the spleen has often been removed from anemic subjects when the anemia was directly dependent on a diseased spleen. This is the rule in Banti's disease. Cases mistakenly termed pernicious anemia have also been treated by splenomegaly. Only recently, however, has a typical case of pernicious anemia been thus dealt with, for the latter has always contraindicated operative intervention. The recent good operative results have led to the belief that pernicious anemia may originate in the spleen as a result of hemolysis. In these cases (the author cites a personal one) extirpation of the spleen was at once followed by an abundant entrance into the blood of the so-called Jolly's corpuscles.

*March* 30, 1914.

**Progress in Syphilis Therapy.**—Citron isolates a number of principles from his study of this subject which serve as a summary. He introduces the term *syphilis asymptomatica* in which the diagnosis is made through the presence of the positive Wassermann. Trypanosome infections are general in type and the spirochetoses which closely resemble the latter are also general—the mere absence of superficial lesions signifies nothing. We must cease to look at syphilis through the eye of the dermatologist. There is an early meningitis, an early aortitis, which make possible the late development of lesions in these localities. We treat the entire organism, not the surface. Fournier recognized this fact many years before the Wassermann, when he stated that superficial cleanness was no evidence of cure. To-day the Wassermann is the measure of the cleanliness of the entire organism (the author believes that the luetin reaction cannot be compared with the former). Treatment today includes not only destruction of the spirochete, but restoration of damaged viscera to a greater or less extent. These two aims are not necessarily conterminous. A drug which is not a spirocheticide may do much to remove the ravages of the parasite. Iodides demand first mention here, although we know that these substances never cure the disease outright, as can mercury. The latter can bring about a cure in the full sense of the word, as shown by the evidence of the Wassermann. But the few cures obtained by this means are but a drop in the bucket when compared with the failures and doubtful results. Salvarsan is also able to cure syphilis in a certain proportion of cases. It lies near, therefore, to combine these remedies, and this the author has done in all desperate lesions—cerebral syphilis, aortitis, tabes, taboparesis, asymptomatic lues and lues congenita in adults. No *restitutio ad integrum* can

be obtained in such cases. The author's treatment was not at all intensive, for he feared the risk of damage from the drugs. Mercury was given in inunctions, under strict personal hygiene. Unlike inunctions in early syphilis these were meant to be given over long intervals. In a few cases of mild stomatitis, the lesions subsided after a brief intermission of treatment. With salvarsan one fears mostly death. The patient who received the first injection of this substance in the author's clinic, died at once and in all there have been five deaths. The patients were all in the most desperate condition and the remedy was given in the sole hope of saving life. Whatever the part played by the injection not one death could be set down to salvarsan. In a number of other cases severe symptoms followed, without death. Some could be attributed to overdoses, or failure to use the remedy properly. The chief contraindications seem to be nephritis, and bronchial or laryngeal catarrh, and especially lesions of the bronchi after recovery from pneumonia, grip, and diphtheria. The author concludes with the aphorism "do not fear salvarsan; fear syphilis."

*March* 17, 1914.

**The Results of Joint Extension.**—Baeyer sums these up as follows: Diminution of the reciprocal pressure upon the articulating surfaces. Rest position of the joints. Changes in the points of contact of the joint surfaces. Reduction of pressure in joints not filled. The soft parts tend to project into the joint cavities. Prevention or removal of contractures. Compression of the contents of a joint by pathological distention of the latter. Mitigation of pain. The nocturnal twitchings which accompany diseased joints cease. The fever of joint diseases abates. Serum is secreted by the joints. The soft parts of the joint undergo hyperemia, as do also the joint surfaces and bones which enter into the formation of the articulations. After the tension of the muscles due to extension has been abated, these muscles also undergo hyperemia.

**Bacteriological Cause of Endocarditis Lenta.**—Kämmerer narrates the demonstration in 1910 by Schöttmüller that a mild, insidious form of endocarditis existed which was due to a special form of streptococcus. The author after extensive researches into this subject recognizes as the exciting cause a microorganism termed by him the *Micrococcus flavus*. The latter is practically unknown in human pathology, although a common saprophyte in the human pharynx. He believes that it may become virulent after repeated attacks of angina. He by no means disputes Schöttmüller's claim for the pathogenicity of the *Streptococcus mitior* in such cases, but denies any specificity on the part of the latter. Other ordinary harmless germs in the tonsils may also become pathogenic. The peculiar "valvotropic" action of such germs can be explained only by the assumption, often confirmed, that a previous lesion of the valves had existed. At present we are justified in speaking of a "flavus group" and a "mitior" group, rather than of individual strains of bacteria.

**Imitation and Induction Diseases of Children.**—Strauch of Chicago contributes a paper on this subject. After certain historical preliminaries, he considers mass affections which are not hysterical. These may occur in institutions, notably in girls' schools. Drowsiness, tremor, screaming, unconsciousness, convulsions, cough, hiccough, imitation of animal sounds, anomalies of writing, etc. An entire institution may suffer from these imitative affections, and this fact, together with the nonhysterical makeup of a large proportion of the scholars, prevents us from calling the epidemic hysteria in the narrower sense. As instances of the results of suggestibility may be mentioned enuresis nocturna, school headache, etc. Much more serious states are traced to imitation or suggestion, occurring as isolated phenomena. To enumerate them would avail nothing for diseases, and anomalies of function may thus appear without limit. They represent a special type of psychogenous affections due to so-called mental contagion and occurring in childhood.

*March* 19, 1914.

**Bacteriology of the Nasal Diphtheria of Nurslings.**—Buttermilch discusses clinical cases of this condition, which are often mentioned as "diphtheroid," "atypical," etc., because true Loeffler bacilli are not found. Nothing is more difficult for a bacteriologist than to draw conclusions from study of nasal discharges; the more he knows the more reticent he is in regard to the nature of his finds. Various bacteria merit collectively the name "pseudodiphtheria bacilli," which differ from the Loeffler germ in one or another respect. The author sought first to test the noses of presumably healthy nurslings in asylums in respect incidentally to the carrier problem. In no less than 16 per cent. he found true Loeffler bacilli. Animal inoculations and the so-called antitoxic control (on guinea pigs) were added to the usual resources for identification. The total material of 65 nurslings is analyzed as follows: There were 3 cases of typical nasal diphtheria, while in 2 fully virulent genuine bacilli were present in healthy noses. In 5 cases a pseudodiphtheria germ was found. These could be termed diphtheroid, or atypic-avirulent Loeffler germs. Presumably the remaining 55 nuslings had normal nasal discharges.

**Changes in the Specific Warfare against Diphtheria.**—Ruppel concludes his article on this subject with the hope that future improvements in von Behring's technique will end by making him another Jenner. He will not only check the ravages of the disease but practically stamp it out. The new remedy, as is known, consists of a mixture of toxin and antitoxin, so that active-passive immunization results. A campaign against the combined carriers in a given locality is the greatest desideratum to-day; and to reach the bacilli which often vegetate in the tissues, a bactericidal serum must be employed.

**Diphtheritic Bacilli in the Viscera in Fatal Cases of the Disease.**—Liedtke and Völckel refer first to the dictum that diphtheria bacilli possess little or no ability to invade animal organs. Quite recently the opposite teaching has begun to assert itself. The bacilli do not all escape by the urine, for many may enter the viscera. This can only be determined by autopsy, so that we are unaware whether such entrance takes place in mild and recovered cases. In any case the discovery of germs in the viscera in the most virulent cases of the disease seem significant. It is therefore a question whether many "mixed septic cases" with invasion of the tissues by pyogenic cocci are not in reality severe uncomplicated diphtheria. The organs found to contain bacilli include heart, lungs, liver, spleen, and bone marrow. Failure of antitoxin in these cases is naturally explained by inability to reach these visceral organisms.

**Icterus in the Course of Puerperal Infection.**—Cyrille Jeannin classifies the causes of this condition as follows: (1) Toxic, including such agents as chloroform, phenol, lysol, etc. (2) Infectious agents, chiefly streptococci, colon bacilli, and the *Bacillus perfringens*.—*Journal des Sages-Femmes.*

# Insurance Medicine.

## SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

### MORTALITY AMONG NEGROES.

THE colored people of the United States have not shown much desire in the past to insure their lives, this disinclination depending chiefly upon a natural improvidence and a lack of means. As the opportunities for education and financial advancement are more commonly embraced by them, they will gradually realize the advantage of life insurance. There must be a material improvement in their social and physical conditions, however, before they can hope to secure life insurance at ordinary rates or with the lower price policies. The only reason for the reluctance of life insurance companies to issue policies to negroes is the high mortality experienced among them as a class. The following table issued by the Census Bureau in Bulletin No. 112, "Mortality Statistics, 1911," is very interesting, giving a comparison in the mortality among whites and negroes.

DEATH RATE PER 1,000 POPULATION, 1911

| | CORRECTED | | | CRUDE | | |
|---|---|---|---|---|---|---|
| | Both Sexes | Males | Females | Both Sexes | Males | Females |
| Washington, D. C. | 18.9 | 20.8 | 17.2 | 18.7 | 21.2 | 16.4 |
| White | 14.6 | 16.4 | 13.0 | 15.5 | 17.8 | 13.4 |
| Negro | 30.5 | 33.3 | 27.9 | 26.6 | 30.3 | 23.5 |
| New Orleans, La. | 21.8 | 24.6 | 19.1 | 20.4 | 23.1 | 17.9 |
| White | 17.5 | 19.9 | 15.3 | 16.6 | 18.7 | 14.5 |
| Negro | 34.0 | 38.8 | 29.6 | 31.2 | 36.2 | 26.9 |
| Baltimore, Md. | 19.4 | 21.1 | 17.7 | 18.4 | 20.3 | 16.7 |
| White | 16.7 | 18.4 | 15.1 | 16.2 | 17.9 | 14.6 |
| Negro | 35.4 | 38.4 | 32.6 | 30.9 | 34.3 | 27.9 |

The corrected death rates are the death rates at all ages that would have resulted from the rates prevailing at the various age groups if the sex and age constitution of the population in the several areas had been identical with that of the population of England and Wales as enumerated at the census of 1901.

The data in this table are strengthened by the experience of life insurance companies as exhibited in the following synopsis of the report of the Medico-Actuarial Investigating Committee.

MORTALITY AMONG NEGROES

| | Number Entering | Actual Deaths | Expected Deaths | Ratio of Actual to Expected Deaths, per Cent |
|---|---|---|---|---|
| Ministers, teachers and other professional men | 4,503 | 202 | 147.4 | 137 |
| All other colored men | 17,296 | 792 | 540.0 | 147 |

One company found a much heavier relative mortality in the later than in the earlier policy years; the statistics are summarized into (a) first to fifth policy years, and (b) sixth and succeeding policy years.

| Policy Years | MINISTERS, TEACHERS AND OTHER PROFESSIONAL MEN | ALL OTHER COLORED MEN |
|---|---|---|
| | Ratio of Actual to Expected Deaths, per Cent | Ratio of Actual to Expected Deaths, per Cent |
| 1- 5 | 141 | 142 |
| 6-24 | 131 | 154 |

The trend of the mortality by ages at entry may be seen from the following exhibit, in which the two classes of negroes have been combined:

| Ages at Entry | Actual Deaths | Expected Deaths | Ratio of Actual to Expected Deaths, per Cent |
|---|---|---|---|
| 15–29 | 160 | 94.1 | 170 |
| 30–39 | 334 | 222.6 | 150 |
| 40–49 | 342 | 226.6 | 151 |
| 50–59 | 149 | 134.3 | 111 |

The above exhibit indicates that the mortality among the negroes insured is relatively highest at ages at entry under thirty.

A recent report by another company which has issued a fairly large number of policies to colored people shows the following:

EXPERIENCE OVER PERIOD OF 60 YEARS, ACCORDING TO AGE AT ISSUE

MODIFIED HEALTHY ENGLISH TABLE

| | Whites, per Cent | Negroes, per Cent |
|---|---|---|
| First policy year | 122.3 | 199.7 |
| Second policy year | 102.2 | 122.1 |
| Third policy year | 94.5 | 116.1 |
| Fourth policy year | 87.6 | 221.6 |
| Fifth policy year | 80.2 | 112.9 |
| First to fifth policy year, inclusive | 97.5 | 158.1 |
| First to tenth policy year, inclusive | 93.3 | 151.7 |
| Grand total | 96.5 | 152.7 |

The figures given in the tables vary somewhat at some ages on account of the small number of entrants represented in a few of the reports at those ages. The exhibits are harmonious, however, in testifying to the excessive mortality among the negroes insured, and this showing is further emphasized by the fact that the deaths among them as reported by the life insurance companies occurred after the risks had been selected with great care.

It is quite evident that there must be a lack of vitality in the race, and that there are contributing causes such as lack of proper conditions and, often, of proper food, morals, and inability to cope with modern conditions. This lack of resisting power may be attributed largely to inherited disease, and is particularly indicated by the tendency to tuberculosis. The writer has been informed on several occasions while visiting the large hospitals in New Orleans, and by reliable physicians in the South, that the blacks are very much more liable than are the whites to succumb to attacks of pneumonia, and that tuberculosis and syphilis are very prevalent among them.

Under the circumstances a company cannot afford to accept negroes on a cheaper plan than a ten, fifteen, or twenty-year endowment, or a rated-up policy, and will even then experience losses unless the most rigid scrutiny is observed in the examination, inspection, and selection. It must always be borne in mind that there is usually more or less doubt as to the age, that the business becomes expensive through a large ratio of lapses, and that they are indifferent in their memory of the personal and family history. These misstatements are usually made through ignorance or carelessness, and are seldom inspired through wilful deceit.

The only individuals who should be considered are those who live with healthy surroundings, are far above the average in intelligence, and are prosperous in their business or follow some one of the professions.

# Book Reviews.

LECTURES ON TUBERCULOSIS TO NURSES. Based on a Course Delivered to the Queen Victoria Jubilee Nurses. By OLLIVER BRUCE, M.R.C.S., L.R.C.P.; Joint Tuberculosis Officer, County of Essex; late Medical Superintendent, Queen Alexandra Sanatorium, London, Canada; late H. P. and A. R. M. O., Brompton Hospital for Consumption and Diseases of Chest. With Illustrations; price $1.00 net. New York: Paul B. Hoeber, 1913.

THIS volume seems to us rather advanced for nurses. There is discussion on theory of immunity, opsonic index, signs and symptoms, diagnosis, prognosis, and treatment, as well as a little on nursing. The book has no index.

DISEASES OF CHILDREN—A Manual for Students and Practitioners. By JOHN MCCAW, M.D., R.U.I., L.R.C.P. (Edinburgh), etc.; Senior Physician, Belfast Hospital for Sick Children; Clinical Teacher of Diseases of Children, Queen's University, Belfast; Lecturer and Examiner in Queen's University, Belfast, 1913-14; Ex-President Ulster Medical Society; Ex-President, Belfast Division, British Medical Association; Author of "Aids to the Diagnosis and Treatment of Diseases of Children," "Aids to Infant Feeding and Hygiene." Price $3.50 net. New York: William Wood & Co., 1914.

VERY few of the recent works on diseases of children have been so ably written with special reference to the practical needs of the student and general practitioner as has this volume by Dr. McCaw. The book is not as large as the average single volume textbook, nevertheless it is complete as well as concise. The chapter on infant feeding deserves special commendation inasmuch as it contains a clear exposition of the many different methods of infant feeding in current use and points out the special indications and relative value of each method. Although an English writer, the author shows an unusual degree of familiarity with the American contributions to this vexed subject of infant feeding. Among the methods described are those of Ashby and Wright, Gaertner, Rotch, Meigs, and Parrot. The chapter on the specific fevers is a valuable one; the author shows in minute detail the differential diagnosis of the various acute infectious diseases in children, illustrating these differences by means of the familiar tables of parallel columns. It is interesting to note that the author adopts a reasonable attitude with respect to the prophylactic administration of antitoxin. He holds that on account of the dangers of anaphylaxis this preventive administration should be restricted or abandoned. At the end of this volume there is appended a chapter entitled "General Information." This chapter contains points of anatomical and physiological interest pertaining to the child and its growth and development; various tables on the teeth, incubation periods, eruptive periods, and quarantine; a description of the various diagnostic methods, dosage, etc. The book contains a series of excellent plates and other illustrations. It is well written, the style being clear and to the point. The subject of treatment is given a greater share of attention than is usual in the average textbook on pediatrics. The book may be recommended without reserve as a valuable guide to the student and general practitioner.

A TEXTBOOK OF THE PRACTICE OF MEDICINE. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of Medicine and Clinical Medicine, Medico-Chirurgical College, Philadelphia. Eleventh Edition. Thoroughly Revised. Illustrated. Price $5.50. Philadelphia and London: W. B. Saunders Company, 1913.

THE fact that it has been necessary to issue eleven editions of this textbook is sufficient evidence that it has found many appreciative readers. An examination of the present revision shows that it has been brought well up to date and that nothing of importance has been omitted. Among the new matter included one notes sections on the parathyroids, on the newer aspects of cardiac diagnosis such as auricular fibrillation, extra systoles, etc., status lymphaticus, and diseases of the thymus gland, antityphoid vaccination, and pellagra. The author still adheres to the view that the latter disease is due to contaminated cornmeal. Among other headings under which radical changes or additions have been made are syphilis, diabetes, gout, leukemia and pernicious anemia, gastric disorders, the treatment of drug addictions, and many more. In these as well as in other parts of the book more or less extensive changes will be found, and the volume is well adapted to the needs of those in search of an agreeably written, reliable, and comprehensive book on general medicine as it should be practiced to-day.

GUNSHOT INJURIES—How They Are Inflicted, Their Complications, and Treatment. By Colonel LOUIS A. LAGARDE, United States Army Medical Corps (Retired), Late Commandant and Professor of Military Surgery, U. S. Army Medical School; Professor of Military Surgery, Medical Department, N. Y. University, etc. Prepared under the Direction of the Surgeon. General United States Army and Published by Authority of the Secretary of War. Cloth; illustrated; 398 pages. Price $4.00 net. New York: William Wood & Company, 1914.

SINCE the character of the so-called hand weapons and the composition of the projectiles used has always been about the same in military and civil life, this subject under the old types of armament has been thoroughly covered by many writers, especially by Otis, whose work was a recognized standard throughout the world. In recent years, however, the universal adoption, in both military and civil life, of the high powered rifle of smaller caliber, employing steel mantled projectiles with an enormously increased initial velocity, and also the fact that the conditions and methods of treatment are far different now than in the preantiseptic days, when most of the standard literature on these subjects was written, has resulted in the demand for an up-to-date, authoritative work based upon practical experience under the changed conditions. Colonel La Garde's book fulfills this requirement and has an added value in that he has presented and compared the characteristic features of wounds under the old and new styles of armament. The first 150 pages of the book cover technical considerations, such as the descriptions of the various types of firearms, explosives, projectiles, etc., which have been used from early times to the present day; characteristic lesions produced by military rifles employing various types of bullets; the wounds from pistols, revolvers, shot-guns, target-rifles, etc.; the symptoms of gunshot wounds; infection; and treatment in general. The injuries of special regions and tissues of the body are then taken up and we find chapters on gunshot wounds of the head, face and neck; spine; chest; abdomen; injury to blood-vessels and nature of the lesions; gunshot wounds of the joints, and of the diaphyses of the long bones. The medico-legal aspects of gunshot wounds are briefly considered, and there is a final chapter on field $x$-ray apparatus. It will thus be seen that all phases of the subject have received attention, and the reader will soon find that the text is remarkably interesting. Illustrative cases are freely quoted and these, together with numerous illustrations, particularly $x$-ray photos, and frequent reference to the work of other surgeons, serve to call especial attention to the most important points.

The work unfortunately contains a number of typographical errors which we shall hope to see corrected in the next edition. They are unpleasant to encounter in the reading, though of course they do not detract from the teaching value of the text. The book will easily fall in the front rank of works devoted to this subject.

GERIATRICS—The Diseases of Old Age and Their Treatment, including Physiological Old Age, Home and Institutional Care, and Medicolegal relations. By J. L. NASCHER, M.D., New York. With an introduction by A. JACOBI. With 50 plates. Containing 81 illustrations. Price $5.00 net. Philadelphia: P. Blakiston's Son & Co., 1914.

DR. NASCHER has made an incursion into an almost virgin field of medical literature, that is so far as the literature of this country or, in fact, so far as English medical literature is concerned. The author is thoroughly competent to write on the subject of old age and its treatment, as he seems to have made a special study of it for a considerable period of time. How to ward off old age has been the goal at which physicians since the healing art was first practised have always aimed. The elixir of life was sought for when medicine was not a science, and now that it is based on scientific principles the object is to conquer disease and thus to prolong life. Pathological old age is discussed in its various forms and treatment suggested. The latter part of the book is taken up with a consideration of the hygiene of old age. The entire volume is interesting and suggestive.

THE PRACTICE OF MEDICINE. A Text-Book for Practitioners and Students with Special Reference to Diagnosis and Treatment. By JAMES TYSON, M.D., LL.D., Emeritus Professor of Medicine in the University of Pennsylvania and formerly Physician to the Hospital of the University, and M. HOWARD FUSSELL, M.D., Professor of Applied Therapeutics in the University of Pennsylvania and Physician to the Hospital of the University, etc. Sixth Edition, Revised and Rewritten. Philadelphia: P. Blakiston's Son & Co., 1914.

IT has been said that no text-book should go beyond the second, or, at the most, a third edition, and this book presents a fairly good illustration of the reasons for such a dictum. The first edition represented an almost purely personal work with all its merits, and was deservedly popular. The present edition demonstrates to what a condition such a work may come after several revisions. The increasing size of the book has forced the exclusion of the historical portion of the work and the homogeneous character of the first edition has been sadly disturbed. In addition, many of the newer advances in medical science have escaped consideration. This is perhaps most marked in the department of therapeutics. No mention is made, for instance, of the use of emetin in the treatment of amebic dysentery or of the intravenous use of salicylates in articular rheumatism, but what is more surprising is that the gastric disturbances following digitalis administration are still regarded as due to the local action of the drug. The sections on Morbid Anatomy are as a rule rather unsatisfactory, in pertussis, for instance, the lesions in the tracheal mucosa are not described. The article on diabetes insipidus has been inadequately revised and no mention is made of the part played by tuberculosis in the causation of pleurisy with effusion, certainly a matter of great importance and general knowledge. On the other hand, there have been introduced entirely new sections on acute anterior poliomyelitis, pellagra, and caisson disease, and there has been a great enlargement of the space devoted to a large number of conditions, especially the infectious diseases. Unfortunately there has apparently been little proofreading, for the text contains almost innumerable typographical errors.

STUDIES CONCERNING GLYCOSURIA AND DIABETES. By FREDERICK M. ALLEN, A.B., M.D. Price $9.00. Boston: Harvard University Press, 1913.

THE twelve hundred pages of this book represent the results of three years' research in the Laboratory of Preventive Medicine and Hygiene of the Harvard Medical School, and no one who examines the volume can help feeling that they were three unusually diligent and fruitful years. In addition to presenting the author's own views, together with an account of the experimental work which led up to them, the book contains a remarkably complete and voluminous review of the literature of diabetes. This alone represents an enormous amount of work, and it has been done so well as to impart real literary value to the result, while from the standpoint of completeness it leaves nothing to be desired. The research work comprised two chief lines of investigation. First, the behavior of sugars in the body; and, second, the production and modification of diabetes. This involved the performance of an extremely large number of experiments on animals which are reported in detail in admirably arranged protocols. In regard to the outlook for the cure of diabetes, the author is very optimistic, for he considers the disease as a functional disorder of the pancreas, which is susceptible of relief by therapeutic measures. His view is that in general, excepting a certain number of distinctly organic cases, the sequence of events in the etiology of human diabetes is as follows: Nervous disorder leading to impaired function of the islands of Langerhans, which in turn entails deficiency in the pancreatic amboceptor resulting in glycosuria with its attending symptoms. In developing this theory he upholds the conception that diabetes is fundamentally a disorder of the sympathetic system and that the pancreas of the average diabetic is functionally still efficient if relieved from the abnormal influence to which it is subjected. Accordingly, the disturbance of the pancreas is regarded as being, at least at the outset, purely functional, while the organ itself is largely or entirely sound. The amboceptor hypothesis is founded on the idea that the sugar of the body is normally in a state of colloid combination. The substance with which glucose combines, or some link in the combination, is contained in the internal secretion of the pancreas. Without the pancreas, this combination cannot be effected and without combination utilization is impossible. The polyglandular conception of the disease does not meet the author's approval, and he characterizes it as arbitrary, confusing, and self-contradictory, preferring to adopt the doctrine of pancreatic insufficiency as the sole and invariable cause of diabetes. Among the procedures proposed as offering a possibility of cure are nerve operations, having as the object the securing for the pancreas of a new nerve supply, or ligation of the pancreatic duct. The latter suggestion is made because it has been found that the occurrence of diabetes after reduction of the pancreas to a remnant of definite size when the ducts are left patent, can regularly be prevented by ligating the ducts. It is stated that under favorable conditions by this means a diabetes already under way may be stopped in experiment animals. The procedure, however, will hardly appeal to those who have seen the effects of pancreatic duct obstruction in cases of fat necrosis. Under the designation of "the dextrose paradox," Allen discusses the fact that in normal animals the more sugar is given the more is utilized, and that there is no limit of the power of utilization of sugar except death This "paradoxical law" makes it possible to distinguish sharply between diabetic animals of every type and non-diabetic animals; for in the former there is a real limit of tolerance. If diabetic animals are given injections of dextrose the resulting increase in glycosuria may not only equal but even exceed the dose administered. The diuretic and antidiuretic effect of sugar given in different ways is also described as affording a test by which diabetes can be distinguished from the alimentary, hunger, toxic, phlorhizin, thyroid and nervous glycosuria. Exceedingly interesting matter is also included in the sections on the therapeutic use of dextrose injections. The book embodies the results of much original work and also provides a valuable compendium of the literature, so that it may be regarded as one of the most important and stimulating contributions to the subject that has yet appeared.

HYGIENE AND PUBLIC HEALTH. By LOUIS C. PARKES, M.D., D.P.H., Univ. of Lond. Consulting Sanitary Advisor to H.M. Office of Works; late Civilian Sanitary Member of the Advisory Board for Army Medical Services; Medical Officer of Health of the Metropolitan Borough of Chelsea; Examiner in Public Health to the Royal College of Physicians and Surgeons, London; Fellow of the Royal Sanitary Institute; and HENRY B. KENWOOD, M.D., F.R.S. Edin., D.P.H. Lond. Chadwick Professor of Hygiene in the University of London; Medical Officer of Health and Public Analyst of the Metropolitan Borough of Stoke Newington and Medical Officer of Health for the County of Bedfordshire; Examiner in Public Health to the Royal College of Physicians and Surgeons, London; Fellow of the Royal Sanitary Institute. Fifth Edition, with illustrations. Price $3.50. Philadelphia: P. Blakiston's Son & Co., 1913.

THIS is one of the best known books on hygiene and public health in existence and the fact that it has attained its fifth edition shows its popularity. The work has been brought up to date in every particular. One chapter on the contagia, communicable diseases and their prevention, and hospitals has been carefully rewritten, and much of it is new. No one interested in hygiene and public health can afford to be without this work.

DIE AUGEN-SYMPTOME DER RAYNAUDSCHEN KRANKHEIT. Von ophthalmologischer Seite literarisch-kritisch bearbeitet von Dr. E. E. BLAAUW, Buffalo, N. Y. Price Mks. 1. Halle a S.: Carl Marhold Verlagsbuchhandlung, 1913.

IN this brochure of 26 pages the author mentions the symptoms of Raynaud's disease, gives a short sketch of Raynaud's career, and describes a case occurring in his practice which presented the symptoms of Raynaud's disease without necrosis, but with ocular symptoms, consisting of irritation of the conjunctiva and lids with diminution of vision, but without the narrowing of retinal arteries as described by Raynaud. This is followed by an extensive review of the literature on Raynaud's disease. The brochure is an interesting contribution to the subject.

# Society Reports.

## INTERNATIONAL SURGICAL ASSOCIATION.

*Fourth Congress, Held in New York City, April 13-16, 1914.*

(Special Report to the MEDICAL RECORD.)

*Monday, April 13—First Day.*

THE PRESIDENT, PROFESSOR A. DEPAGE OF BRUSSELS, IN THE CHAIR.

**Addresses of Welcome.**—Dr. WILLIAM C. GORGAS, Surgeon-General, U. S. A., said that he had been sent by the President as a representative of the Government to welcome the congress to the United States and to express his regrets that he could not be present in person. Both the President and the United States Government considered it the greatest honor to have this International Congress in America. It was a stimulus along surgical lines in every direction, and it was not only a great honor but would be of great benefit to all.

Dr. WILLIAM J. MAYO of Rochester, Minn., said that as President of the American Surgical Association it was his privilege to express to the members of the Congress in the name of that organization a welcome to America. They were pleased that for the first meeting of the International Surgical Association outside of Brussels they should choose a typical American city for their meeting place. They owed Europe a great debt as she had laid the foundation of medical and surgical science upon which they had built. It gave him great pleasure to express their gratitude and to acknowledge this debt. He had often been asked if they had a typical American surgery, and he replied "No," for they were dependent on European and English surgeons for so much and had brought back such great inspiration from the clinics of Europe that they had not an American but a cosmopolitan surgery in this country. They welcomed them as their Alma Mater come to see what they had accomplished, not only in New York but in Philadelphia, Baltimore, Montreal, Chicago, Rochester, Minn., and even in New Orleans, and if they found merit, that merit was a compliment to Europe.

Professor CHARLES WILLEMS, Chairman of the International Committee, being absent, his address was read by Dr. J. P. Hoguet, American Secretary of the Congress. He expressed the hope that at the next meeting, which would be held in Europe, they might have the pleasure of meeting many Americans. The remainder of Professor Willems' paper was a memorial to the members of the Association who had passed away during the past three years and an account of the achievement of each.

Dr. LEWIS J. MCARTHUR, Chairman of the American Committee, said that it was fitting that a society born in Brussels should be greeted with the following cablegram: "I send hearty congratulations and best wishes for the Congress. (Signed) The King of Belgium." He said that they had just listened to a long list of losses that they had incurred since the last congress. His duties had fallen upon him through the death of Dr. Roswell Park and it was fitting that they should recall the memory of a man who had done so much to inaugurate this group. There had been international surgical congresses before but none with the scope of this one. It was a pity that after having worked so hard to gather together these master minds, he could not have lived a few more days in order to have participated in this his fondest hope. There were differences in the boundaries of countries but the science of surgery knew no bounds; the world was its field. There was sometimes some discussion in the pursuit of knowledge, but in certainty there would be unity.

**President's Address.**—Professor A. DEPAGE said that the first meeting of the International Surgical Congress took place in Brussels; they gave it preference to a neutral country so as to clearly define the scientific, and at the same time fraternal, character of their Association. It was not necessary for him to tell that it was the privilege of their little Belgium to offer a meeting place for the learned men of all nationalities, covered by Europe itself with the shield of peace and liberty. How did they accept without hesitation the cordial invitation to America? Such an important decision was not justified by merely the deep esteem they felt for their surgeons or by the most legitimate curiosity; it was influenced chiefly by the certainty that they would receive a welcome prompted by the most noble sentiments of scientific fellowship. Belgium asserted pacific tendencies by her political neutrality; America favored treaties by arbitration which were the triumph of right over might. She organized her scientific institutions and her universities which assured more and more the victory of intellect over force and chance. The surgeons necessarily represented a mute and constant protest against the evils of war. They impressed upon all that war was the greatest of scourges. The surgery of war owed much to America. In 1861 the Sanitary Commission appointed by Lincoln played an important part in the course of events; it was the great artery which carried the love of the American people to the army. Since fifty years new duties had arisen with which it was of importance that the surgeons of all countries should reckon. They should be employed in perfecting their sanitary organizations. With them rested the task of developing the organization of their war surgery so that it might remain on a level with the sad needs of their times. American surgery here again had furnished them with important illustrations. The international understanding should be reinforced more and more by the organization of help for the victims of war; this was a thing greatly to be desired. Without doubt such an understanding already existed; the Red Cross was the most striking illustration of this. At the time of the last Balkan war they saw ambulances which came from all countries. This international fraternization was without doubt an encouraging sight. The Balkan war had only just emphasized the lesson taught by the Manchurian war; the fate of the wounds depended more upon the side which was given in the front of the battle, for as long as the engagement lasted, the exposed ground was inaccessible for the ambulance men of whom more than one had sacrificed his life in spite of all precautions taken; thus hours passed during which the men remained without help. The following was without doubt the solution of the problem: Eeach of the combatants must carry with him side by side with his cartridges the articles necessary for the first dressing. This solution had already been accepted and taken into use in different countries. The experience of late wars had proved only too clearly that before all the sanitary education of the soldier must be improved. He must realize the dangers of infection by earth, dust and water; he must know that it case of a wound in the abdomen it was better to remain motionless, even for hours, than to walk as far as the station. The military structure of a soldier in the future would not be complete unless it comprised an acquaintance of the necessary measures to take for his personal safety and especially the elementary rules of asepsis and antisepsis. The making general of these instructions would result in a great saving of human life. One should not leave the giving of first aid to the injured to the ambulance men, for often they arrive too late. During the Balkan war the Turkish army doctors and others tried to extract the bullets and amputate in the ambulance at the front and they were able to certify that on the arrival of the wounded at the hospitals of the town the greater part of these interventions had produced deep-seated suppuration. In the hospitals of the second line, which never changed place whatever happened, the operations could be performed that were judged indispensable. There experienced surgeons should be placed who should decide the serious questions and pressing interventions, should they be carried out in these hospitals of the second line. Civil consultant surgeons should also be attached on regular duty who would insure the utmost caution at the critical moment. These tried surgeons should oppose the performance of all operations of which they did not clearly see the urgency. The man surprised by traumatism could oppose less resistance to a general shock than another who had had time to prepare and arm his organism. During the last war a fact which had filled all surgeons with astonishment was the comparative harmlessness of the modern gun. He said that he had seen bullets which had pierced the arm or leg sometimes throughout their whole length, and others the abdomen or the breast or even the back of the brain, without producing infection of any serious consequence. At the same time the effects of the cannon had become more deadly than ever. As surgeons they would not reproach the modern gun for not killing

his man with every shot; what they desired was to reduce the so-called "efficiency of the shrapnel." At a meeting of the Imperial Surgical Congress at Constantinople in December, 1912, the fervent wish was expressed that the use of shrapnel might be abolished on the same grounds as the explosive bullet. Those who had been brought in close contact with the dreadful miseries of this poor human race, found it more and more difficult to understand why men did not employ their reasoning powers to a good end by ceasing this destruction of one another. They hoped to see the "United States of Europe" in friendly intercourse with the "United States of America," and they reserved their deepest admiration for those who were working to assure universal peace.

Amputation of the Arm and Forearm.—Professor Oskar Witzel, Düsseldorf, said that the indication for an amputation could only be fixed if one was in touch with all the modern resources capable of assuring the preservation of wounded, diseased, and deformed limbs. The introduction into surgery of the antiseptic treatment of open wounds, contusions and fractures by von Bergmann allowed the postponement of amputation in time of war as well as in ordinary practice. The processes of suture resection, anastomosis, and transplantation of the blood vessels enabled the preservation of parts of limbs wounded or affected by arteriosclerosis. In cases of infected wounds Bier's method of prophylactic hyperemia and his method of hyperemia together with small carefully made incisions in the suppurating parts, preserved limbs in which septicemia and pyemia would otherwise have demanded amputation. Modern operative orthopedy restored the power of useless limbs by means of osteotomy and musculo-tendinous transplantation. In cases of simple tumors and even in myeloid sarcoma, excision followed by transplantation was more than justified. Even in malignant tumors the adjunction of radiotherapy and chemotherapy allowed the hope of a less radial position than formerly. Amputation of itself could never endanger life and should procure for the patient a useful and painless stump. The danger of the actual operation was decreased by increasing the resisting powers of the patient, whether the case was one of emergency or not, by complete arrest of hemorrhage in cases of accident, by strengthening the heart by the use of camphorated oil, saline infusions, inhalations of oxygen, application of heat, respiratory exercises, etc. The choice of an anesthetic, the preservation of warmth during the operation, and Esmarch's tourniquet were also important factors. General anesthesia was preferable on account of the psychic effect resulting from amputation. Hackenbruch's process was suitable for minor operations and Fraun's endoneural anesthesia for bigger removals, always with the addition of discipline in the working of the operating theater. Bier's rachi-anesthesia would rarely be indicated. After the operation life would be saved by simple and thorough asepsis. The section of tissues should be clean; in order not to injure their vitality it was necessary to work with gentleness, heat, and moisture. For this end the use of antiseptics must be rejected, and there must be strict hemostasia. Cardiac tonics and respiratory exercise judiciously applied prevented thromboembolism. To obtain a painless and serviceable stump clean section should be made above the nerve stumps; in disarticulation and epiphyseal amputation, avoiding the opening of the marrow canal prevented the formation of neuritis by fixation of the nerve roots on the surface of the sectioned bone; sealing the marrow canal by the process of Bier, Wilms, Ritter, or Bung also prevented this accident. Massage of the soft tissues and early utilization of the stump in temporary prostheses served the same purpose. For a good utilization of the stump as a lever for prosthetical apparatus, regard should be taken of the unequal retraction of the muscles and tendons. The suture of neighboring muscles and those of opposing ones between themselves, helped to maintain the functional equilibrium. Certain tendinous groups, particularly in the forearm, might be transferred into rings covered anew with skin giving a most life-like prostheses. The creation of levers possessing active movements, and digital autoplasty, gave hope of remarkable success.

Amputation of the Leg.—Dr. J. F. Binnie of Kansas City, Mo., said that the level at which amputation of the leg was performed below the knee had no influence on the vital dangers of the operation; hence the choice as to the method and site of such an amputation depended upon the lesion for which the operation was required and on the use that was to be made of the resulting stump. No particular improvement had been made in the methods of amputating below the ankle joint. If gangrene was the occasion for the amputation, the site of operation would depend largely on the extent of the vascular disturbance and this was determined by the use of Moschowicz's method of examination or by Sandrock's method, which was much simpler. The use which was to be made of the stump was a factor of prime importance in the choice of a site of amputation. If the financial condition of the patient was such that he could not indulge in a more or less expensive artificial limb, then it was of vast moment to save as much of the limb as possible and to provide him with a good stump, one that would withstand abuse and on which the weight of the body could be supported without harm resulting. The types of these operations were Symes' and Pirogoff's. If the patient could afford a good artificial limb it was better to amputate at a higher level so that there might be room between the stump and the ground for such an apparatus. The improvements attained in amputations of the leg were all in the attainment of better weight-bearing stumps and the designs of artificial limbs must in the future adapt themselves to these improvements. Hirsch and Bunge's periosteal treatment of the bony stump in any amputation, and osteoplastic amputations under particularly favorable circumstances, were very valuable means toward obtaining ideal weight bearing stumps. All the advantages of Bier's operation could be easily and safely obtained by covering the cut end of the tibia with a free transplant of bone. One proceeded with this operation in the following way: By any of the customary methods (preferably a flap method) reflect the soft parts and so expose the tibia covered by its periosteum for a few inches below the proposed line of bone section. Transversely divide the periosteum of the tibia along two lines separated from each other by a space of about one-half inch greater than the diameter of the bone. From the upper incision separate the periosteum downward for about one-half inch. From the lower incision separate the periosteum upward for about one-half inch. Cut through the cortical bone of the tibia transversely at the base of the periosteal flaps. With an osteotome or Gigli's saw cut free the plate of bone between the transverse incisions. This plate of bone is covered by periosteum which hung from its upper and lower edges like a tablecloth. Preserve this in warm salt solution. Complete the amputation by sawing through the bones after forming a periosteal cuff on the tibia. Place the plate of bone over the cut surface of the tibia and fix it there by periosteal sutures. The tibia and the plate might be united by chromicized catgut sutures introduced through drill holes instead of by periosteal sutures. If desired the bone plate might be made long enough to cover the cut surfaces of both tibia and fibula, extending between them like a bridge. As had been already stated, such an operation as the above was entirely out of place unless asepsis could be assured and the resisting power of the patient was satisfactory.

Amputation of the Leg and Foot.—Dr. M. Durand of Lyons, France, read this paper. He said that any one of the three middle toes might be amputated by disarticulation of the second phalanx, by metatarsophalangeal disarticulation, or by amputation in continuity of the first phalanx. These operations did not alter the function of the foot. No other operation was recommended. These conditions also applied to the small toe. The great toes were amenable to all operations in continuity and contiguity. Total disarticulation, especially if carried out by the subperiosteal method, gave excellent results. The walk was but slightly affected by the simultaneous disarticulation of the five toes. As to the metatarsal bones, amputation of one of the last metatarsal bones in continuity or by disarticulation left but small difficulty. The disarticulation of the first metatarsus was a little more serious from the functional point of view. It had not, however, the disadvantages ascribed to it. The subperiosteal method was particularly favorable in this case. More than two of the metatarsal bones must not be amputated. Transmetatarsal and tarsometatarsal amputations, according to Lisfranc, gave generally excellent functional results. Amputations and disarticulations which affected the anterior tarsus without suppressing it entirely must be recommended. Chopart's disarticulation was an excellent operation; it risked a reversion of the stump and it could, if not

entirely proscribed, at least be reserved only for very exceptional conditions. Ricord's operation and subastragaloid disarticulation were both excellent and had practically the same value. The osteoplastic operation on the posterior tarsus (Sebiliot, Pirogoff, Pasquier-Lefort) preserved the normal bearing upon the plantar tissues and furnished also very good results. The tibiatarsal disarticulation carried out according to Ollier's subperiosteal method gave supple and enduring stumps. It left such good functional results that it might be considered equal to the greater part of the more conservative operations of the posterior tarsus. Of supramalleolar amputations and amputations of the lower third of the leg, it might be said that they were of slight mutilation rendering means of provision of solid skin tissues obtained from the heel; they sometimes permitted the direct bearing of the stump extremity on the prosthetical apparatus. They had a usefulness very similar to the tibiotarsal disarticulation because of the length of the leg lever and the power of the muscles which they preserved. Amputations of the middle third of the leg did not admit of the terminal weight bearing if performed according to classical methods. There was some hope that the former osteoplastics would improve in their results. Amputations of the leg above the middle part had ceased to deserve the name of "amputation at the seat of election" and should be performed only when the extent of the injuries did not permit of a lesser sacrifice. Larry's intracondylar amputation was preferable to the disarticulation of the knee. Amputations of the leg and foot owed their gravity to the affection which necessitated their performance and to the general condition of the patient. The progress of surgical technique and of asepsis had enabled a more correct adaptation of the stumps to the prosthetical apparatus and considerable increase of the utilization of these stumps. Prosthetic apparatus in their technical realization had considerably improved the utilization of stumps in amputations of the foot and especially of the leg. Owing to this progress they could now usefully perform amputations of the middle and lower third of the leg.

**Amputations of the Leg and Foot.**—Dr. E. RANZI of Vienna read this paper and concluded as follows: (1) The most important condition for the portability of the stump was formed by the removal of the excessive formation of callus on the surface of the stump. Bier and Wilms avoided the same by closing the marrow hole, the former using a flap of periosteum and bone, the latter with sinew; Bunge accomplished the same result by the removal of the periosteum and endosteum on the lower stump. (2) The removal of the cut outside portable surface and the prevention of adhesions between the soft parts and the stump were of less importance for the portability of the stump. (3) Of the methods that were most sought after for portability, that of Bunge seemed to be the best for war surgery as in times of peace, because on the one hand it was the simplest and on the other the results were the best if no "*prima intentio*" occurred. (4) In every method of operation it was of the greatest importance for the results that the patient take walking exercises and had massage, as well as to put his weight on the wooden leg as soon as possible.

Dr. DEPAGE of Brussels said that without question one of the greatest advances of modern surgery in time of war was the substitution of a more conservative surgery for the brutal amputation formerly in use. During the Crimean War on the French side in 22,521 wounds of the extremities 6,577 amputations were done. On the side of the English in the same war there were 777 amputations in 4,764 wounds. During the war of the Secession there were more than 30,000 amputations done, and in the Franco-Prussian War the percentage was higher still. Since this time surgical operations on the field of battle had become more and more rare and since their danger was understood amputations had become exceptional. The conditions of the surgery of war were of a special nature in that the ambulance service was often controlled by young practitioners impatient for action and eager to perfect themselves in the art of operating, while in the civil hospitals the surgeons were experienced men who had the time necessary to apply the appropriate methods of treatment, being able to operate on a chosen day and according to that method which appeared best for each individual case. During the Russo-Japanese War the surgeons in chief, Vreden and Haga, interdicted all operations on the field which were not absolutely necessary, and it was not otherwise in the last war at Constantinople; the central committee of the Red Cross Society took severe measures to moderate the zeal of some young surgeons. It should be repeated on every occasion that the wounded man in times of war had more right than any other man to their protection. The field of battle should not be a field of experience for the surgeon. The practice of amputation in times of war might be divided into three categories: 1. Primary amputations. 2. Intermediate operations. 3. Secondary or tertiary operations. The primary operations were necessitated by the extent of the lesion and the imminent peril to life; these were the only amputations that should be performed on the field of battle. They were formerly numerous and their results were nearly always fatal. The immediate treatment of wounds should be limited to the prevention of infection and hemorrhage. Applications of iodine dressings and tamponing with a solution of zinc chloride (10 per cent.) had been found useful for this purpose. Intermediate operations were those practiced between the second and ninth day, when the chance of infection had passed. At this time one should be very careful before deciding to sacrifice a limb on the first manifestation of fever. In the ambulance service which they had directed not a single amputation was done because of suppuration following a wound by a projectile. Most of the amputations were done because of grave infection following gangrene of the foot. These gangrenes were not caused, as was formerly thought, by coagulation, but by compression or by the infiltration produced by the edema consecutive to the long marches across wet and marshy ground. At first sight it would seem that amputation was urgent in these cases, but this was not always so; sometimes continuous lavage, friction with alcohol, and some days' rest in bed would result in the disappearance of the edema. When in the presence of a gaseous gangrene amputation became urgent. In doing an amputation for gangrene the concern of the surgeon was not so much whether to do an osteoplastic or a periosteal operation, but rather how he might secure the best nutrition possible. Often one did not suture, or the flaps were but closely approximated so as to assure perfect drainage. Chloride of zinc dressing was useful after operations for gaseous gangrene. Secondary and tertiary amputations were practiced when the primary wounds were healed, and were necessitated especially by deformities, retracted cicattrices, nuerites, etc. Here one found the patient in a better condition of resistance and the choice of method might be left to the judgment of the surgeon, who need not here follow the rules of war surgery, but could be guided by general hospital practice.

Dr. A. LAMBOTTE of Brussels said he did not use an Esmarch's bandage for amputations as was formerly done in all operations of this nature. In operations on the thigh it rendered hemostasis long and difficult. In place of this bandage he used three or four ligatures to keep the field dry. After making the primary incision he went directly to the femoral vessels and clamped both the femoral artery and the femoral vein. In addition to these vessels it was necessary to ligate two or three of the muscular arteries. When operated on in this way there was no bleeding after the operation. In amputations of the foot the best method was by the subastragalian disarticulation of Roux. This method had given him success in twenty cases. The cicatrix was well placed and the amount of shortening was minimized. He had had recourse on one occasion to a dermoplastic operation after the method of Keetley for an incurable ulcer of the leg and had secured a perfect result.

Dr. ZAHRADNICKY of Nemecky Brod said that in all they had had 255 cases of amputations of the larger joints with 23 deaths or a mortality of 9 per cent. They had done the following amputations on the upper extremity: transmetacarpal, four with no mortality; Metacarpal, five with no mortality; hand, three with no mortality; antibrachial, 24 with two deaths; brachial, 25 with two deaths; interscapular, four without mortality, making in all 65 cases with four deaths. The amputations done on the lower extremity were as follows: femoral, 60 with 10 deaths or a mortality of 16.6 per cent.; crural, 70, with five deaths, or a mortality of 7.1 per cent.; femoral, according to Gritti, 46 with three deaths; foot, according to Pirogoff, 10 without a death; according to Syme, one without death; according to Chopart, one with one death; according to Lisfranc, one without a death, and

one metatarsal without death, making 190 cases with 19 deaths or a mortality of 10 per cent. The highest mortality was from gangrene, there being 12 deaths in 31 cases operated upon, or a mortality of 38.7 per cent.

Dr. W. H. HUTCHINGS of Detroit laid stress on the desirability of saving as much of the limb as possible and called attention to a method which had given him marked success. In infected cases they opened freely and made an autogenous vaccine which was administered as soon as possible. For a dressing they used six per cent. salt and one per cent. citrate of sodium in distilled water and kept the dressing soaked. This, together with the increased bactericidal power of the blood produced by the vaccines, he believed had saved many patients. His experience had covered 500 hand injuries, of which 100 were treated by ordinary methods and the remainder by this method, and he had found that by this method the end results were better and the convalescence shorter.

Dr. WILLY MEYER of New York called attention to the possibility of avoiding amputation, especially in endarteritis in young people, by means of hyperdermoclysis of Ringer's solution according to the Ito-Kobar method. Dr. Meyer cited several instances in which this method had proved effective. The dose was 400 to 500 c.c. at each injection and the injections were given in various locations. In the juvenile forms of gangrene one should first try hyperdermoclysis with Ringer's solution; if this failed, then one might attempt an arteriovenous anastomosis, and only after both of these had failed should one resort to amputation.

Dr. M. L. HARRIS of Chicago said there were two classes of cases in which the mortality was high. These were operations on the aged for gangrene and in severe crushing injuries involving the thigh. In such cases amputation should be done under nerve blocking rather than under general ether anesthesia. With the nerve blocking the operation could be done without the slightest shock.

Dr. WILLIAM L. ESTES of South Bethlehem, Pa., said that in considering the advisability of operation one should take into consideration the blood pressure. When the blood pressure was 80 mm. or lower it was useless to operate; when it was above that figure operation might be attempted. This was an important index to the advisability of operation, especially in crushing injuries. The two other points were asepsis and the securing of a field as bloodless as possible. To obtain the latter he no longer used constriction but the gradual dissection method, beginning at Poupart's ligament in operations on the thigh, dissecting carefully and tying the vessels as he proceeded. With the gradual dissection method there was no oozing afterward. Out of 724 amputations he had done few by the subperiosteal method, and nearly always used a periosteal flap. Of this number only 18 cases came to a second operation, either from ulcer, pain, or inability to use apparatus. The nerve should be cut four, five, or six cm. above the section of the bone. He had found Chopart's operation useful. Out of 42 transtarsal amputations, he had used Chopart's operation 36 times, and all the patients did well.

Dr. STEINTHAL of Stuttgart gave a lantern slide exhibition of *x*-ray pictures showing the varieties of bone stumps secured by different methods of operation.

*Tuesday, April 14—Second Day.*

PROFESSOR SONNENBURG IN THE CHAIR.

The day was devoted to discussion of gastric and duodenal ulcers.

**The Diagnosis of Gastric and Duodenal Ulcers.**—Dr. F. DE QUERVAIN of Basel presented this paper, which was read by Dr. Henschen of Zurich. The writer reviewed the present status of the clinical and radiological diagnosis of gastric and duodenal ulcer. All who were concerned with gastric surgery were familiar with the well established facts and with the modern advances in the radiological diagnosis of ulcers of the stomach, so he passed over these and stated the questions which were still under discussion and upon which it was hoped the present discussion would throw some light. The following were some of the questions: (1) What was the frequency of spasm in the superficial ulcer of the lesser curvature? Under what conditions did this spasm occur in the absence of any ulcer? (2) What influence had ulcers removed from the pylorus on the latter? (3) What were the surest and most practical distinguishing signs between pyloric spasm and pyloric stenosis in the beginning? (4) What was the diagnostic meaning of the persistent repletion of the duodenal bulb? (5) What was the semiological value of the duodenal movement of the stomach? (6) What differentiation was there between duodenal ulcers encroaching upon the pylorus, true pyloric ulcers, and duodenal ulcers of low situation from the point of view of their action on the pyloric reflex and on the gastric chemism? (7) What were the surest radiological signs of the adhesions from the stomach and the duodenum?

**Ulcer of the Stomach and Duodenum.**—Drs. H. HARTMANN and P. LECENE of Paris presented this paper, which was read by Dr. Hartmann. They stated that duodenal ulcer was certainly more frequent than was thought some years ago; nevertheless its frequency had been exaggerated, and in France at the very least they noticed on an average one ulcer of the duodenum for eight or ten ulcers of the stomach. They thought that the clinical criterions, the symptomatology described by Moynihan and the anatomical signs (pyloric vein) were far from being above criticism. Moynihan's symptomatology was that of pyloric spasm, and the pyloric vein was very unreliable both as regarded situation and disposition. At the base of the callous ulcers of the stomach, which were situated especially on the lesser curvature, lesions of neuritis were frequently found, accounting for the persistent pains which were one of the principal elements in the symptomatology of these ulcers. The cancerous evolution on the borders of callous ulcers of the stomach did not appear to them as frequently as certain writers had upheld. They agreed with Hayem that the carcinomatous evolution on the borders of the ulcer were noticed in about one-fifth of the cases of callous ulcer. This frequency was still great enough to justify the treatment of these ulcers by resection when it was possible. The examination in a certain number of cases of fragments of the gastric wall taken at a distance from the ulcer had very often shown (twenty-five times out of thirty) the existence of lesions of gastritis, either parenchymatous, hyperplastic or mixed, both parenchymatous and interstitial. This proved that in ulcerous cases one had most often to deal with gastric tissues wholly diseased, and in this lay the great importance of postoperative medical treatment in these cases. The importance of radiography and radioscopy in the diagnosis of gastric ulcer was universally recognized. With a good technique, avoiding the causes of mistake, a great part of the radioscopy could be printed especially for the diagnosis of penetrating callous ulcers, such as Haudeck's recesses, stomachs bilocular from ulcer, ulcerous pyloric stenosis, and perigastritis. The value of the *x*-ray in the diagnosis of ulcer of the duodenum appeared to them to render less service. The surgical treatment of gastric or duodenal ulcer must not be opposed to the medical treatment; the first was only the frequently necessary complement to the second. The real results of the medical treatment, observed after a lapse of time, were far from being as good as was formerly supposed. All gastric or duodenal ulcers showing resistance to medical treatment belonged to the surgeon. Posterior gastroenterostomy with a short jejunal handle, performed on the pyloric cavern itself at its most sloping point, seemed to them to be the operation of choice in all cases of juxtapyloric ulcers of the stomach or duodenum. The objection to this operation, namely, the nonfunction of the passage if the pylorus was pervious, appeared unfounded. Experimentally and clinically it had been shown that the gastrointestinal passage functioned perfectly if care was taken to make it exactly on the pyloric cavern. The indications for the exclusion of the pylorus needed still to be more clearly shown; the simple blockage of the pylorus was generally sufficient, the absolute exclusion being limited for certain cases. In cases of pyloric callous ulcers, when a cancerous degeneracy was suspected, it was preferable to have recourse to pylorectomy when anatomically possible, closing the two edges and finishing by a gastroenterostomy. In cases of callous ulcers of the small curvature simple gastroenterotomy was often shown to be inefficacious; it was better in these cases to have recourse to excision of the ulcerous zone, either by excision limited to the ulcer of the small curvature or by segmentary resection of the stomach with suture end to end of the two gastric edges. The still fairly high mortality of these gastric resections would certainly decrease in proportion as their indication and technique became more clearly defined.

**Chronic Ulcers of the Stomach and Duodenum.**—Dr. WILLIAM J. MAYO of Rochester, Minn., gave an historical review of his subject, dividing it into three periods.

The first period from 1893 to 1900 only those cases showing marked pyloric obstruction were operated upon. During the second period from 1900 to 1906 their knowledge grew rapidly as the result of surgical observation. In the third period from 1906 to 1914 there had been a marked development and improvement in diagnosis. In considering the present status of their knowledge Dr. Mayo stated that up to December 31, 1913, 1,841 cases of acute and chronic ulcers of the stomach and duodenum had been operated on in St. Mary's Hospital. Of this number 457 were females and 1,384 were males. The early clinical view of a preponderance of females over males was thus shown to be an error. In 636 of the 1,841 cases the ulcers were situated in the stomachs and in 1,205 in the duodenum. The percentage in the last 1,000 cases accurately observed showed 73.8 per cent. duodenal and 25.2 per cent. gastric. Of the gastric 29 per cent. were females and 71 per cent. males. Of the duodenal 21 per cent. were females and 79 per cent. males. In differentiating between an ulcer in the pyloric end of the stomach and one in the first part of the duodenum the situation of the pyloric veins was the factor. The terminal three-fourths inch of the pyloric end of the stomach was not often involved in the ulcer. The more common seat of gastric ulcer was along the lesser curvature, more often in the posterior than on the anterior wall. Multiple ulcers were not frequently found at operation. Multiple ulcers of the stomach and duodenum or separate ulcers of the stomach and duodenum existed in the same case in about 5 per cent. of the cases. The character of ulcers of the duodenum differed in many respects from those of the stomach. A large number of acute, subacute and chronic ulcers were cured permanently by medical treatment, but if the cures failed to show permanency after a reasonable attempt at cure under ordinary conditions of life the patients should be treated surgically. The patient with ulcer treated medically was in far greater danger of death from hemorrhage, perforation, obstruction, or cancerous degeneration than he was from an operation. Gastrojejunostomy was the most generally useful operation for gastric ulcer and had a wide field of application. Especially was this true when the ulcer was in the vicinity of the pylorus. It might be said that the greater the obstruction within limits the more immediate and permanent the results of gastrojejunostomy. This operation changed the physiology of the stomach and brought a greater measure of relief than could be achieved without it. Posterior jejunostomy was the operation of choice, but adhesions might prevent its use in certain cases. For those ulcers which were in the body of the stomach and in which gastrojejunostomy must be made beyond the point of ulceration the results were less favorable. Local excision of the ulcer without gastrojejunostomy had in their experience failed sometimes to effect a cure and therefore, as a rule, gastrojejunostomy should be done in addition to excision. When a resection in a continuity of the stomach with end to end union had been made for chronic ulcer the results had been excellent without gastrojejunostomy. The results of their operations in duodenal ulcer were extraordinarily good, 98 per cent. of the patients being either cured or greatly relieved by the operation. In these operations they had used the Heineke-Mikulicz pyloroplasty, or what they had found still better the gastroduodenostomy of Finney. They had abandoned continuous silk sutures in gastrojejunostomy and were now using interrupted musculoperitoneal sutures of fine silk with continuous chromic catgut for the inner rows. In cases where fixation of the pyloric end of the stomach about an ulcer had continued to give rise to much pain after operation the unilateral pyloric exclusion of von Eiselberg as a secondary operation had given permanent relief.

**Etiology, Pathology, and Operative Technique of Gastric and Duodenal Ulcers.**—Dr. E. PAYR of Leipzig presented this communication, which was read by Dr. Juarez of Leipzig. He stated that there were two principal theories in regard to the etiology of these ulcers: (a) that of a gastric or duodenal vascular lesion, such as thrombosis, embolism, or sclerosis, and (b) a nervous origin by vasomotor spasm leading to a localized ischemism of the mucus. Neither of these theories was sufficient to explain every case and many points in gastroduodenal biological chemistry were still unexplained. Some mechanical causes played a part in the localization and the form of the ulcers. The bacteriotoxic lesions had also a certain part. There were two types of duodenal ulcers, according to their position on the posterior or anterior wall. The first presented a tendency to perforation and the second to hemorrhage. Between the ulcer of the duodenum and that of the stomach there existed very appreciable anatomical chemical differences. It was actually impossible to establish the frequency of the cancerous transformation of a gastric ulcer, or to establish before the operation a decided distinguishing diagnosis between callous ulcer and gastric cancer. Ulcer of the duodenum very rarely showed carcinomatous degeneration. The callous ulcer of the stomach should be resected every time that the general condition of the patient allowed it, especially when it was a question of small ulcers situated at a distance from the pylorus at the lesser curvature and on the posterior surface. In all other cases posterior gastroenterostomy constituted the operation of choice. The excision of gastric ulcers generally gave unsatisfactory results unless accompanied by gastroenterostomy. The excision or the resection of duodenal ulcers should be exceptional except in the presence of persistent hemorrhage, imminent perforation, or suspected cancer. For duodenal ulcer the best intervention consisted of a gastroenterostomy combined with a unilateral pyloric exclusion after von Eiselberg's method. If this operation was not feasible the best way was to shorten the pylorus by means of an aponeurotic band or a suspensory ligament. It was necessary to bury the band under a seroserous continuous suture. The exclusion of the pylorus might be combined with a suspension of the stomach. If a neighboring ulcer of the pylorus was resected at the same time as the latter the stomach should be sutured after the method of Billroth. For ulcers of the lesser curvature and those of the posterior surface total segmentary resection with axial suture of the stump gave the best results. For certain cases of ulcers near the pylorus, especially with the rate of acidity increased, after the resection there should be a wide implantation of the gastric stump in the first jejunal handle after the technique of Reichel. This process perhaps guarded against peptic ulcer. If the latter occurred resection was advisable. Very wide anastomosis between the stomach and the duodenum after the technique of Finney also perhaps guarded against this accident. Clinical confirmation of this relied upon a too restricted number of cases. Gastroenterostomy for simple callous ulcers necessitated a consecutive treatment of atropine and alkalines for at least a year. Gastroenterostomy gave excellent results in cicatricial stenosis of the pylorus. In active ulcers distant from the pylorus the results were less reliable. Only in from 50 to 60 per cent. of these cases was the result satisfactory. The mortality in resection of ulcers, especially by the total segmentary technique of Reidel, was 10 per cent. or less. It remained, however, higher than that of gastroenterostomy, but to this must be added the later deaths from perforation, hemorrhage, etc. The clinical results of resection were good.

Dr. A. LAMBOTTE of Brussels said that it was clearly established that pyloric exclusion constituted an important supplementary procedure to gastroenterostomy. Of all the methods devised to effect this exclusion the simplest was by ligature of the pylorus. In his work he had had recourse to this procedure for several years. It had been objected that the occlusion thus obtained did not remain, but that the ligature fell into the intestinal cavity. The ligature could be applied so that this would not happen. If the thread was drawn to the point of arresting the circulation of the blood it could not fail to produce a section of the tissues and with the aid of peristalsis there would not be much delay in expelling the ligature into the intestinal cavity. When the ligature was loosely drawn, just sufficiently to bring the mucous membranes into contact, the thread would not be drawn into the intestine. He had not had occasion to verify by sight the permanence of the occlusion thus effected, but he had been able to prove its efficiency by using it in intestinal surgery. Each time he made an enteroanastomosis he closed the excluded end by a simple ligature placed in such instances some centimeters below the artificial anus. In the latter case he had been able to verify the permanence of the closure several months later. He applied the ligature after the gastroenterostomy was completed. The ligature was drawn very slightly, as it was necessary that the thread should have some play on the tissues. Linen thread was employed and the ligature placed habitually over the sphincter, which was located by palpation. The great advantage of this method was its extreme simplicity, the entire procedure taking only a few seconds. After this method of pyloric exclusion there need be no fear of hemorrhage, and furthermore it could be used in the

weakest patients. As to peptic ulcers Dr. Lambotte believed that it was necessary to seek their origin in the operative technique that had been followed rather than in the pathological disposition of the patient. He had encountered only one case in more than six hundred operations on the stomach. He was convinced that traumatism of the mucous membrane produced by instruments or by the fingers of the operator were responsible for peptic ulcers, and this would also explain the variation in the observations of certain surgeons, some having a variable percentage of peptic ulcers and others never observing any.

Dr. Charles L. Gibson of New York cited statistics which Dr. P. R. Turnure had collected from the Hudson Street, Roosevelt, and St. Luke's hospitals during the past eighteen months. During this period there were seventy-four cases of perforating gastric and duodenal ulcer operated upon. Of these forty-seven were gastric and twenty-seven duodenal ulcers. There were sixty-six males and eight females, showing that contrary to the former belief the condition was more frequent in men than in women. The ages ranged from eighteen to sixty-two years. The average age of the fatal case was forty years. The number of days spent in the hospital averaged nineteen. There were twenty-six cases that came to operation within twelve hours after the perforation; of these sixteen were cured and ten died. There were seven cases that came to operation from twelve to twenty-four hours after perforation, and of these one was cured and six died. Three cases came to operation in from twenty-four to forty-eight hours after perforation; of these two were cured and one died. Twelve cases came to operation after forty-eight hours; of these four were cured and eight died. The complications in the order of frequency were subphrenic abscess, pneumonia, gastric hemorrhage, secondary adhesions, and empyema. Out of forty-eight cases sixteen broke down between the seventh and twelfth days. Gastroenterostomy was done in seventeen instances; of these fifteen were cured and two died.

Dr. Sonnenburg of Berlin considered the frequency with which duodenal ulcer occurred and the results of operation. They had had eighty cases in their clinic. The diagnosis of gastric or duodenal ulcer was by no means a very simple matter. In cases of recently perforated duodenal or gastric ulcer the history was rarely characteristic. In chronic cases pain was frequently absent. In ten cases of perforated duodenal ulcer there were five who gave no history of gastric disturbance whatever, and in three the gastric disturbance was noted for only a few days or a week. Moynihan called attention to the characteristic history of periodic attacks of hunger pain with intervals of apparent well-being. This had been absent in many of their cases. On the whole the history was more characteristic in the chronic cases. The pain in the right side of the abdomen near the umbilicus which had been mentioned as characteristic was frequently absent or found in other abdominal regions. Similarly there were other symptoms which had been considered characteristic of ulcer which were found in other conditions. Increasingly good results from operative treatment would accrue as operative technique improved and diagnosis became more accurate through radioscopy. After reviewing the opinions of different authorities on the value of radioscopy the speaker said that Max Cohn had stated that stiffening of the ventricle and too rapid emptying of the stomach were in no sense pathognomonic but only accompanying symptoms of gastric and duodenal ulcer, but that retention of bismuth in the duodenum was of great importance. Abnormal gas formation in the duodenum was of special import, especially gas bubbles in the first portion of the duodenum. In his personal experience the bismuth test had not been absolutely reliable. The majority of physicians in Berlin agreed that the diagnosis of duodenal ulcer remained a probable rather than an absolute diagnosis. In regard to the relative frequency of gastric and duodenal ulcer their experience was at variance with that of American surgeons. In his series of cases there were thirteen duodenal ulcers and sixty-seven gastric. The information given by Moynihan and American surgeons had helped him to make a diagnosis in many instances. A low leucocyte count was of grave diagnostic import, indicating a virulent infection. Arneth's method of blood examination was of special value as determining the reserve power of the organism in its fight against infection. Although the blood examination in these ulcers was not of as great value as in peritonitis and appendicitis, it should not be neglected. In his experience the mononuclear leucocytes fell rapidly to normal limits in the favorable cases, while in the lethal cases they remained high to the end. The leucocyte count was of value in the differential diagnosis as it was inconstant and fluctuated more in cases of ulcer than in appendicitis. Peritonitis following perforating ulcers often ran a benign course with encapsulation of the abscess. In the later course of the disease the leucocyte count indicated the treatment to be followed.

Dr. Arthur Dean Bevan of Chicago spoke of the work that Dr. Rosenow had been doing in relation to the etiology of ulcers. This work showed the selective activity of certain microorganisms or strains of microorganisms for certain anatomical localities. With certain strains of microorganisms Dr. Rosenow had produced endocardial lesions in animals; by others he had produced arthritis in the joints, and by other strains lesions in other parts of the body. In ten or twelve instances cultures from duodenal ulcers had been introduced intravenously into animals and had produced typical gastric and duodenal ulcers. This selective action of certain microorganisms was not the only factor in the production of gastric and duodenal ulcers; in addition, the lowered resisting power of the individual and the local condition due to the corrosive action of the hydrochloric acid played a part in the etiology of these ulcers. Dr. Bevan emphasized the enormous possibilities of proper medical management in gastric and duodenal ulcer, and thought that by absolute attention during every hour of the twenty-four for weeks many of the cases could be cured by medical treatment that had hitherto been referred to the surgeon. He also called attention to the importance of proper medical care after the surgical operation. The patient who received proper medical management after operation had an earlier and smoother convalescence. The unfortunate results after operation for gastrojejunal ulcer might be largely prevented by proper medical management.

Dr. John B. Murphy of Chicago said he wished to supplement Dr. Bevan's report. The points presented had long been observed from the clinical standpoint. Primary acute attacks of gastric and duodenal ulcer bore a definite relation to other conditions in the body. Dr. Rosenow had taken the *Streptococcus viridans* and cultivated it in six different media and thus had changed it rapidly in its physical conditions and relations and its results in the production of pathological lesions. From clinical observations alone it seemed evident that gastric and duodenal ulcers were practically metastatic lesions. This was illustrated by their occurrence at that season of the year when infections of the upper air passages were most frequent and they also ran the classical course of such infections. In regard to operative technique, Dr. Murphy said that after employing the round button in former years he then practised the suture method for a time but had returned to the button; not the round button formerly used but an oblong one. By using this button in making the approximation hemorrhage was an impossibility. He first placed in a running row of sutures, then inserted the oblong button, and then continued the sutures.

Dr. Howard Lilienthal of New York emphasized strongly the necessity of removing the entire ulcer-bearing portion of the stomach when it was located near the pylorus. He had been led to take this stand by his experience with three cases operated on by the Finney method in which a careful inspection at the time of the operation revealed nothing abnormal but in which a cancer developed three years after the operation. The added risk of removing the entire danger zone was less than leaving it for future operation when cancer should have developed. When the patient was in good condition the entire ulcer area could be excised at one operation but where there was an indurated mass and one could not see where it began, the best procedure was to do a gastroenterostomy with the minimum amount of manipulation. Then after about three weeks the tumor could be removed and a pylorectomy performed. This was the best method in selected cases with indurated ulcers and gave a lessened mortality.

Dr. A. G. Gerster of New York said that with gastroenterostomy and a pyloric exclusion they sometimes had recurrences, and that even in resection of the pylorus the cure was not always permanent. There seemed to be no sure way of interrupting permanently the passage of the food through the digestive canal.

Pyloric exclusion, no matter how established, did not secure against the reestablishment of communication. He cited one case in which after a posterior gastro-enterostomy fluoroscopic examination showed the food passing from the stomach into the duodenum. Repeated fluoroscopic observations had been made and there was no question as to the correctness of their observations. After operation the patients experienced relief but they were not cured as the ulcer was due to a condition that they did not understand and unless operation was reinforced by proper dietetic and hygienic measures the relief was only temporary.

Dr. Willy Meyer of New York pointed out the uncertainty of reliance on a pathological examination at the time of operation and urged the necessity of excising the entire ulcerous area. He also cited an instance in which he did a gastroenterostomy in a man of sixty years. The man was now seventy-one years of age but had had several hemorrhages at intervals during the period since operation and these might have been avoided if pyloric exclusion had been practised. The two-stage operation might be a good thing in some cases, but when every minute counted and the patient had all the signs of hemorrhage they should exclude the pylorus entirely. A modified Jianu operation and the use of Hultl's instrument which provided a firm compression of the tissues to be divided with rapid, easy, and safe placing of a double row of wire staples between which division was made might be applicable in certain operations on gastric and duodenal ulcers.

Dr. A. J. Ochsner of Chicago said that experiments on animals had shown that it was very difficult to establish gastric or duodenal ulcers unless the animal was first rendered anemic, or unless certain strains of microorganisms were introduced according to the method of Rosenow, or unless the circulation was very much interfered with. When they found in normal persons and in animals a condition in which it was so difficult to establish ulcers, this should be accepted as absolute proof that in the development of their methods of treatment provision should be made for restoration from a very severe condition. This was also confirmed by the histories of these cases. That they have habitually abused normal feeding was confirmed by the history in all of these cases. There had been long continued irritation due to hyperacidity in the peptic ulcers. Such a combination of conditions rendered the alimentary canal more or less septic. The patient had swallowed septic material perhaps from the teeth, the pharynx, or the tonsils, for years. These were some of the factors which had kept up conditions favorable for the establishment of ulcers, and they corresponded with the conditions in which it was possible to establish experimental ulcer. Consequently in the preliminary treatment they had found many cases seemingly incurable in which if alkalinity was established and maintained, and anemia and faulty feeding overcome, a cure had been effected and maintained. When the patient was in a depraved physical condition the two-stage operation was of the greatest importance.

Dr. William L. Rodman of Philadelphia said that everyone had believed for many years that gastro-enterostomy had its limitations; while patients made operative recoveries clinically they were not cured. Six or twelve months, or two years later, they would develop subphrenic abscess, hemorrhage, or cancerous degeneration, and it therefore seemed that if there was any more radical treatment, and if it could be employed without increasing the operative risk, it ought to be considered. An additional reason for this statement was found in the fact that the most experienced operators confessed their inability to differentiate between ulcer and cancer at the operating table. In the majority of instances in which a condition was pronounced ulcer it proved later to be cancer. They had been kept from removing the entire ulcerous area by an exaggerated idea of the operative mortality. Recently he had communicated with one hundred surgeons asking for statistics on this subject and about fifty had answered. Altogether 378 radical operations had been done; in 204 cases pylorectomy had been done and in 174 excision in the large part of the stomach. The mortality in all was a little more than 5 per cent. (5.4 per cent.). The mortality of the pylorectomies was about 8 per cent., and that of excisions in the large part of the stomach less than 2 per cent. He felt that if they took Dr. Lilienthal's advice and performed the two-stage operation in cases that were poor risks the mortality could be kept down to 5 per cent., because a careful analysis of the mortality tables had convinced him that many deaths were due to the bad judgment used in subjecting patients to pylorectomy when they should have had a preliminary gastro-enterostomy and then a pylorectomy later would have given satisfactory results. Ulcers did not so often become malignant in the cardiac portion of the stomach.

Dr. Mayo referred to the splendid work of Dr. Rosenow but stated that there were some things that required further experimental work. It had been shown that if they fed colon material to animals they got acute lesions. Strains of streptococci had produced acute ulcers but they had not produced chronic ulcers. Some ulcers seemed to be chronic from the beginning. They had been making some experiments to find out if obstruction was a factor in causing ulcers to become chronic. If cancer developed on an ulcer it was never in the base but always in the overhanging margin, and where the cancer was found in the base it could be assumed to have been cancerous from the beginning. If ulcers were within one to one and one-half inches from the pylorus they were essentially duodenal. If a one-stage operation could be done, it should be done; the two-stage operation was not for every case, but only for the poor risks.

Dr. Brüning of Giessen said that the symptom-complex described by Monyihan occurred in many cases of ulcer of the stomach but was absent in others. There was no way in which one could be absolutely certain as to the location of the ulcer. It was very important that the field of operation should not be subjected to much manipulation or traumatism. The von Eiselberge Ausscholtung method of operation was undoubtedly the best. It was a method that he had often used, and that had given him good results. It was his practice to cut around the entire stomach musculature down to the mucous membrane a little above the ulcer. About this was laid a fascial strip which was pulled firmly and sewed in a ring. Over this the muscular serosa was again joined. A gastroenterostomy on the anterior pylorus ended the operation. By ligating the pylorus according to the method of Wilms no food could irritate the ulcer. Furthermore all peristaltic waves were retarded. The automatic peristalsis, acting as in experiments in animals, showed itself first lower down and did not become more marked and irritation from the food was obviated. It was important to keep the stomach contents alkaline as acid increased the peristaltic action. Only small amounts of food should be given as large amounts caused an expansion of the stomach which in turn caused a response in the form of a contraction wave. In this way he endeavored to keep the entire field in the vicinity of the ulcer at rest.

*Wednesday, April 15—Third Day.*

Dr. Hartmann in the Chair.

The day was devoted to papers and discussion on grafts and transplantations.

**Grafts in Plastic Surgery.**—Dr. H. Morestin of Paris read this paper. He stated that grafts and transplantations had enabled them to remedy many grave deformities, had led to restorations that had hitherto seemed impossible, and held out hope for a future of marvelous progress. In proof of this the author reviewed the actual treatment of the principal injuries and deformities for which plastic operations were employed and noted the changes that had been made in the results by cutaneous, cartilaginous, and fatty grafts. Free cutaneous grafting succeeded fairly well when a small fragment taken from a soft thin skin and deprived of its pannicule was applied on a strictly aseptic living surface. These indications remained very limited, especially in reparatory surgery of the face on account of the trophic disturbances of the graft and the yellowish or whitish coloration which the graft preserved indefinitely. The Italian method was applicable in cases in which it was absolutely impossible to find at hand the materials for a restoration which allowed the use of all the thickness of the skin and not only of its superficial layers. However, it must remain an exceptional method even for rhinoplasty and blepharoplasty. Its triumph was in the reconstruction of the lobule and the partition of the nose by the help of the skin from the palmar surface of the hand. Dermo-epidermic grafting had innumerable indications in the treatment of superficial wounds, and especially of those which by their extent prevented true methods of autoplasty, as great loss of substance following burns, traumatism, removal of tumors, etc. They alone

enabled the healing of wounds caused by the tearing and complete destruction of the scalp. They were particularly recommended after the excrescences of cancers of the skin in old people. In the surgery of lupus they constituted a last resource, and they promised but mediocre results in the cure of deformities by scar. Dermo-epidermic grafting combined with other methods of autoplasty might be advantageous. The grafting of hairy parts was attainable either by free transplantation or by means of a fragment, this last method being much more preferable, and the only one to be recommended for an important grafting. By this means the eyebrow, and even the moustache, might be restored. The transplantation of cartilage constituted one of the most remarkable innovations in reparatory surgery. By its means the problem of total rhinoplasty had been solved. The difficulty of establishing a framework had been solved. Cartilage constituted a trustworthy material. It was constantly adopted provided it was entirely included. It showed great power of absorption, preserved its life during an indefinite period, and was the only one of its kind among transplanted tissues. This stability rendered it valuable for the construction of the nasal framework. Doubtless other restorations would be benefited by cartilaginous grafting in serious destruction of the facial structure. In incorporating fragments of catilage with cutaneous pieces, gaps in the jaw and in the soft parts surrounding could be filled up. Adipose graftings were excellent for filling up empty spaces, bony hollows, depressions of soft parts, and therefore rendered great service in the repair of cranial gaps and facial deformities. Fatty tissue with few blood vessels and almost inert was one of those most easily transplanted from one place to another. The transplant was almost always made use of, not that it continued to live, for after a more or less short struggle it succumbed, but it was replaced progressively by tissues of new formation to which it served as a protection. The power of procuring fat, and the great ease with which it could be used in all deformities caused by depression, the beauty of the results obtained by operations destitute of all gravity, made this form of grafting a very valuable acquisition to esthetic and reparatory surgery.

Vascular Grafts.—Dr. E. VILLARD of Lyon stated that there were two kinds of vascular graftings, extemporaneous grafting and the grafting of preserved vessels. A grafting was autoplastic, homoplastic, or heteroplastic according as it was taken from the subject under treatment himself, from a subject of the same sort, or from a subject of a different sort. The result of a graft was to be appreciated from both the macroscopic and the microscopic point of view. It was possible to have an excellent functional result allowing nothing to be seen from the anatomical side of the graft and yet the microscope might reveal profound lesions on a segment macroscopically healthy. From the point of view of the technique to be followed Carrel's process gave the maximum of guarantees. Arteries transplanted on the same animal healed without modification, the segment grafted acquiring new life in its new surroundings with the histological structure which characterized it. Arterial homoplastic grafts gave good results macroscopically, but the histological lesions remarked after the lapse of some time placed reservations on the vitality of the vascular graft transplanted from one animal to another of the same sort. Arterial heteroplastic grafts were possible, but it appeared that the graft served only as a protection to a process of reparation on the part of the animal undergoing the grafting. Venous grafts were possible but more difficult to realize with success than arterial graftings. The grafted venous segment became hypertrophied, and underwent histological changes which seemed a step toward the arterial structure. The best process of preserving vessels for grafting was in a physiological and aseptic environment maintained at a temperature of zero Centigrade. Some vascular fragments thus preserved might be grafted with success, but only their elastic frame was grafted which was susceptible of being absorbed by the cellular elements rising from the grafted subject. Vascular grafting might be applied to human surgery in the course of vascular traumatism, in the extirpation of a tumor adherent to the large vessels, and in the cure of aneurysms. If the indications existed to perform a vascular grafting in a man, one would have recourse by preference to an autoplastic grafting, more particularly to a venous grafting, the organism more easily supplying a venous than an arterial graft.

Grafts and Transplantations.—Dr. ULMANN of Vienna presented this paper which he summarized by saying that the hopes raised fifteen years ago on the future of transplantation of tissue and organs had only been partially realized. Heteroplasty seemed to meet with anaphylaxis as its principal obstacle, whilst homoplasty encountered the biochemical properties of the individual. Autoplastic transplantations alone gave good results, while heteroplastic transplantations with the exception of bony tissue always gave bad results. Besides the bone itself did not remain but was replaced by the bony tissue of the grafted material. The results of homoplastic transplantations were variable; given an identical quantity of sanguinous serum from the cellular protoplasm of two subjects in the same condition, homoplasty might probably give as satisfactory results as autoplasty. Further research was needed on this subject.

Grafts and Transplantations.—Dr. E. LEXER of Jèna presented this paper and gave a lantern slide demonstration of preparations from his clinic. He declared that the various tissues employed in grafting were differently appreciated by practitioners and by pathologists. An excellent clinical result might be preserved not only if the graft took, preserving its entire structure but also if it disappeared, giving place to tissues of substitution, and sometimes if completely surrounded by adhesions. The graft might be expelled in cases of failure, by a violent reaction, or disappear in a slowly progressive suppuration, or it might disappear before the process of substitution had taken place, or the substitution might confine itself to the formation of scar tissue. The cause of failure apart from suppuration rested principally in the existence of small blood clots which prevented the transplanted part from becoming normally established. Some of the conditions necessary for a good implantation were vitality, nutrition, powers of acclimatization, and the strength of the transplant for sufficient regeneration, as well as the condition of the wound on which the transplant was made. From a technical point of view scrupulous asepsis, a watch against hemorrhage, a careful manipulation of the grafts, and the absence of lines of suture on their surface must be exacted. The speaker considered epidermic and cutaneous transplantations and pointed out as new the simple transplantation of the skin without epidermis. The value of epidermic and cutaneous homoplasty was very slight and its results doubtful; most frequently it was a question probably of cicatricial substitution or subcrustaceous healing. The speaker also considered the clinical results of the transplantation of mucous membranes, muscular, nerve, and vascular tissues, tendons, aponeurosis periosteum, bone, cartilage, and joints.

Transplantations of Organs.—Dr. ALEXIS CARREL of New York read this communication. He stated that it had been definitely established during the last few years that autoplastic transplantations of organs were practically always successful, that homoplastic transplantations were nearly always ultimately unsuccessful, and that heteroplastic transplantations were always unsuccessful. Autoplastic transplantations of the kidney had been performed with complete success in dogs. It was found that in most instances the animal remained in excellent health. A female dog that underwent a double nephrectomy and the reimplantation of one kidney remained in perfect health, had a number of pups and died of an intercurrent disease almost two and one-half years after the operation. Miscroscopical examination of the kidney showed that it was entirely normal. By this and similar experiments it was definitely proved that the extirpation of the kidney, its perfusion with Lock's solution, the complete interruption of its circulation, for fifty or sixty minutes and the suture of its vessels and ureter did not interfere with its function. In homoplastic transplantations of the kidney the results were different. After six or seven days albumin appeared in the urine and the kidney became congested. After twenty-five or thirty days there was a great deal of albumin and even hematuria in one case. After seven or eight months the albumin disappeared but the kidneys were found to be in a sclerotic condition. When the animals underwent a bilateral instead of a unilateral nephrectomy they always died within a few weeks. It was probable that by using animals closely related, such as mother and son, better results could be obtained. The present aspect of the problem was to find out the causes of the reaction of an organism against a new organ and to discover by what means this reaction

could be prevented and the organ become adapted to its new owner. Some of their experiments indicated that general infection in animals seemed to prevent the reaction of the organism against the new organ, and it was thought that the factors which were instrumental in the reaction of the organism against foreign tissues were the same as those used to fight a general infection, and that when this mechanism was engaged in fighting a general infection the transplanted organs were able to become adapted to the new organism. A very important study of this question had recently been made by Dr. James B. Murphy of the Rockefeller Institute. Dr. Carrel outlined these experiments which had seemed to make it probable that it was the action of the spleen and of the bone marrow which allowed the organism to fight efficiently the foreign tissue which had been transplanted on to it, and that when the action of these organs was less active a foreign tissue could develop rapidly after it had been grafted. It was not possible as yet to foresee whether or not these experiments would lead to the practical solution of the problem presented by homoplastic transplantations. The surgical side of the transplantation of organs was now completed, as they were now able to perform transplantations of organs with perfect ease and with excellent results from an anatomical standpoint. But as yet these methods could not be applied to human surgery, for the reason that homoplastic transplantations were almost always unsuccessful from the standpoint of the functioning of the organs. All their efforts must be directed towards the biological methods which would prevent the reaction of the organism against foreign tissue and allow of the adtptation of homoplastic grafts to their host.

Dr. John B. Murphy was particularly interested in Dr. Lexer's paper and especially with that part which concerned the reconstruction of joints. For the restoration of a joint it was necessary that there should not only be non-union, but a sliding joint and functional restoration. In the reconstruction of the knee and hip it was necessary in addition that the joint should be able to support pressure. These requirements were met by reconstructing the bones on their original conformation by the means of transplants and by the interposition of fascia covered with fat. He had succeeded in reconstructing an ankylosed knee by the detached fat fascia but he had not used it in the hip.

Dr. Depage communicated the results of some experiments made by his assistant, Dr. Danis, on the restoration of the biliary canal in dogs by means of a segment of the jugular vein. In the first series of experiments M. Danis sought to restore the wall of the gallbladder by the application and suture of a graft taken from the wall of the jugular vein. In a second series of experiments he had substituted a segment of the jugular vein for a portion resected from the choledochus. The restoration of the vesical wall by the application of the venous graft succeeded in most instances and the operation was relatively easy, the cicatrization being operative in assuring the vitality of the graft. From the histological point of view the external surface of the transplanted vein recovered a new endothelium. On the internal surface the mucous membrane developed little by little on the graft and finally entirely covered it again. The substitution of a segment of vein for a portion of the hepatic duct was more difficult to effect. After making a number of unsuccessful attempts Dr. Danis succeeded in establishing communication between the hepatic canal and the ampoule of Vater by the interposition of a segment of the jugular vein. The anatomicopathological examination of specimens several months after the operation proved the vitality of the venous grafts and their perfect transformation into a biliary canal. Evidently one could not conclude absolutely that the results obtained in dogs would be identical in human beings, but it seemed without dubt that these attempts could be extended in a sense to the surgical point of view.

**Treatment of Scars.**—Dr. Leonard Freeman of Denver related his experience in dealing with reddened and hypertrophied scars which were especially disfiguring when they occurred about the neck. It had occurred to him that these scars were frequently aggravated by the tension exerted on them and as one could not permanently eliminate them by excision, he had, after excising the scar, introduced a strip of fascia lata from the thigh, fastening it with catgut sutures. When the patient turned the head to the opposite side the strip of fascia lata did away with the tension and when the head was in the normal position the scar became a mere line.

Dr. Porter of Boston said he had had an unusually large experience in dealing with $x$-ray burns, especially among $x$-ray workers, and that transplantations in these cases offered many difficulties. He had found the following method especially suitable to that senile condition of the skin, due to exposure to the $x$-ray, which preceded more serious degeneration. Under gas oxygen he excised the graft area and applied a fine mesh cheesecloth with pressure. This he left in place for two or three days. He then removed the gauze and irrigated the part with normal salt solution and the bleeding stopped in a few minutes. He then cut the graft and allowed the patient to come out of the anesthetic. The graft did best if it did not overlap. When the graft was in place he again applied pressure for twenty-four hours and then dressed the part witb benzoate of lard and some antiseptic. He did not advise this method in the precancerous stage.

**Arterial Anastomosis.**—Dr. Alexis Carrel said he did not think that Dr. Villard had given an accurate idea of the results in the suture of arteries and veins. Venous anastomosis was comparatively easier than arterial anastomosis, especially when the vessels were not of equal caliber. As to the condition of vessels in cold storage, Dr. Villard believed that they lost their vitality and acted only as a scaffold for new vessels. On the contrary, with proper technique the vitality of the vessels could be retained in cold storage. The period of storage could even be of long duration under proper conditions. They now had for the first time a laboratory for the storage of human tissue for grafting purposes under the charge of Dr. Markoe. There the tissues were stored under proper conditions and the storage could be prolonged.

**Nerve Transplantation.**—Dr. K. A. Mackenzie of Portland, Ore., said there had not been much reference made to the value of nerve transplantation. He had had an unusual opportunity five or six years ago to test the value of neuroplasty when there was a large defect in the peripheral nerves. He had a patient who had von Rechlinghausen's disease and developed a tumor on the sciatic nerve as a metastasis. A resection of the nerve below the gluteus maximus resulted in pronounced trophic disturbance of the extremity. Something had to be done so he made an anastomosis between the internal and external popliteal nerves which had a striking effect on the trophic disturbance, changing the whose aspect of the limb. He later split the external portion of the popliteal nerve and buried it in the muscle. After three or four months there was some sensation and after eighteen months the man could walk with unaided locomotion. He thought attention should be called to the value of an operation of this kind.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, Held March* 19, 1914.

The Second Vice-President, Dr. L. Emmett Holt, in the Chair.

This meeting was held under the auspices of the Committee of Public Health, Hospitals, and the Budget.

**The Nutritive Significance of Different Types of Foodstuffs.**—Professor Lafayette B. Mendel of Yale University presented this communication. (See page 737.)

**Nutrition from the Energy Standpoint.**—Dr. Graham Lusk read this paper. (See page 740.)

**The Changes in Food Caused by Canning.**—Dr. W. D. Bigelow of the National Canners' Association, formerly of Bureau of Chemistry, U. S. Dept. of Agriculture, said that the modern method of manufacturing did away with spoiled foods and told of the changes in composition caused by canning. A canned food was a cooked food, and was preserved in nearly as fresh a state as when cooked as was possible. Manufacturers of food or other commodity were usually well satisfied with their wares; if you attempted to criticize a manufacturer you received scant courtesy. Because of constructive work he had come much in contact with the canning industry. He called attention to certain fundamental principles in canning which must be followed, if they were varied even to the slightest extent difficulty would result. The cooking or sterilizing would kill the yeast and the majority of the ordinary bacteria, but there were certain

forms that were not killed. Under some circumstances the enzymes still remained as was shown by three or four illustrations. The food should be gathered at the right degree of maturity and taken to the cannery which should be sanitary. The whole operation should be sanitary. The can should be well filled and heated before capped and all should be sterilized before being cooled. The can was heated to expell the air before canning. The ends of the cans sometimes swelled for other causes than decomposition. The contents of the can bulged but did so without the presence of decomposition. As cold weather came on the ends of the can became concave and showed no decomposition. There was a certain action on the metal by the fruit and as a rule hydrogen was generated. The canners had studied this problem very carefully and had learned the reasons for this swelling and there were at least a dozen. However, the can with the "swelled head" was always open to suspicion.

Dr. MARSHALL CARLETON PEASE said that he regretted very much the absence of Dr. May E. Pennington, Chief of Food Research Division, Bureau of Chemistry, U. S. Department of Agriculture, Washington, D. C., who was now in Texas, because she could have given them an interesting paper on the effect of refrigeration and cold storage on food. He said that next to heat refrigeration or so-called cold storage was the best preservative of foodstuffs. In the preservation of food by refrigeration there were applied the same principles which were employed in the preservation of food by canning. Before refrigeration the food must be normal, must be sound. Dr. Pease referred to two general types in the refrigeration of foods. First, the one that was old and of long usage, the application of low temperatures by means of ice or ice and salt; second, the more recent type, the artificial temperature which could be obtained by mechanical refrigerating processes. Such temperatures brought the food to the criohydric or dessication point and foods could be kept at this point for a considerable length of time, even for years, and come out practically in the same condition as they went in. If one could correlate the temperature, the length of time and the character of the food at the time of storage, one might predict how long food could be kept in a sound condition. Dr. Pease said that his interest was more in a series of fish, especially flukes and flounders, and in the bacteriological examination of the same. This work he had done was with the aid of Prof. Geist. The latter found no change whatever that could be determined by chemical or physical examinations of the fish that had been in cold storage five, nine, or sixteen months. There were practically the same number of bacteria present in the fish at different times during these periods. He thought it better that housewives should obtain their fish in the frozen state and allow them to thaw after purchasing.

Professor SHERMAN of Teachers' College agreed thoroughly with what Dr. Lusk had said regarding the desirability of placing on the label of every package, can, glass, or jar, containing food a statement as follows: "This contains 'x' thousand calories of which 'y' per cent. are proteins of grade A, B, C or D." He spoke of the results of laboratory experiments to determine the amount of the different food elements necessary for proper nutrition of the amounts of the different elements in different proprietary foods, and the results of their administration. There was no greater danger in a deficiency of nitrogen and sulphur than there was in a deficiency of phosphorus, calcium, or iron. Statements made regarding this point had been misleading. The speaker emphasized the importance not only of having the proper constituents in our food but of having them in the proper proportion.

Dr. HAVEN EMERSON spoke of the educational methods, carrying the information which the laboratory workers had gathered to those who greatly needed it. The most important function in the country at large was the understanding of the value of foods, the value of food based on its caloric good. He hoped the speakers of the evening would prepare leaflets telling of certain foods; these should be for publication and would save many from the effects of their ignorance.

**To Abolish the Office of Coroner.**—The Council recommended to the Academy for favorable action, Assembly Bill, introductory No. 905—"An Act to Amend the Greater New York Charter, to create the office of Chief Medical Examiner, and abolish the office of Coroner."

## Miscellany.

**Suggestions for Medical Bookkeeping.**—Sir John Collie believes that every one who has any private income, however small, should keep two banking accounts at the same bank. The first, No. 1, is his ordinary current account, into which he should pay all the money he receives, whether he has been paid in cash or checks. It is an excellent rule never to spend a penny which has not come to one through his banking account. The physician should never get checks which have been paid to him cashed by the local tradesman. He should never pay his chauffeur with his midwifery fees. Every single item received from the physician's practice from one year's end to another should go through his banking account No. 1. If the physician has been tempted to use a five dollar bill which someone has paid him unexpectedly on a round, or if he has bought stamps with the money which some patient left at the office, then he should draw a check for the amount, cash it, and pay the money into his bank. Thus, and thus only, can he make his banker his bookkeeper.

If the physician should die suddenly or wish to sell his practice, then, and then only, whether his other business books are kept well or not, the lawyer or the medical agency, or the purchaser who wades through his effects, will rejoice to find one method of knowing the gross receipts and getting some idea of the real intrinsic value of the business, and will from the physician's bank book alone tell the total cash receipts from the practice upon which to found the purchase price.

At the end of every year the books should be balanced and if the doctor cannot balance them himself, or has not the time, the comparatively small sum which a professional accountant will charge, say five or ten dollars, will be well repaid. If the physician is to keep the end ever in view before him, he must know definitely in black and white if his car, garden, or domestic expenses are increasing. If they are, then he will at least stop and think why this is so and whether he is getting the *quid pro quo*, whether indeed he can afford it, and above all, whether this increase in expenditure is preventing provision for a rainy day. In short, proper bookkeeping teaches one to live within one's means. It has also incidentally the advantage of helping one to render a proper return to the Income Tax Commissioners. The physician's annual balance will of necessity show the charges properly made against his business. He will thus protect himself against over-assessment by the Income Tax Commissioners. Surveyors of taxes are very apt to form extravagant opinions of professional men's incomes, and assess accordingly. It is very difficult to upset such assessment without proper books of account.

The author assumes that the doctor under consideration is a successful man, but it is equally, if not more, important for the struggling practitioner, who, do what he can, is unable to make both ends meet, that he should be in a position to know positively and without any chance for self-deception whether it is worth his while to struggle on in the endeavor to make success of a failure that is absolutely certain to come sooner or later.—*British Medical Journal.*

### THE DEVELOPMENT OF COMPLEMENT-FIXATION TESTS *

By CHARLES CLYDE SUTTER, M.D.,

ROCHESTER, N. Y.

For complete understanding of the principles of the Wassermann, and allied reactions, it is necessary to know what is meant by deviation of the complement. We must also have a general knowledge of antibodies and their relation to immunity, agglutination, precipitation, cytolysis, bacteriolysis and other phenomena.

Very early in the history of bacteriology the bactericidal properties of the blood attracted attention. In the presence of infection certain reaction products are developed in the infected individual. These reaction products may also be produced by the injection of bacteria into the body of an individual. The presence of these substances determines the defense or reaction of the individual. This immunizing process may be due to the action of the cells or of the fluids, or of both. If the process affects the cells we describe the result, cellular-immunity; if it affects the fluids, humoral-immunity. The substances formed in humoral-immunity may be divided into: (1) agglutinins, (2) precipitins, (3) complement-binding substances and (4) opsonins. This paper will only discuss the humoral-immunity as it directly leads to an understanding of the complement-fixation tests.

These reaction bodies due to the presence of infection or by the parenteral introduction of bacteria, cells and other substances have been called by Ehrlich, antibodies. Some of them are protective to the individual; others have but little apparent protective influence; and still others sensitize the subject.

The current explanation of the formation and mode of action of these antibodies is that given by Ehrlich and is known as the lateral-chain or side-chain theory. His theory, although purely empirical, has proved so adaptable that it has been greatly amplified and extended to other related problems. Its remarkable usefulness in this field places it among the great theories of science. His theory accounts for the development of antibodies by supposing that the receptors which combine with the specific antigens are, under certain circumstances, provided in excess and are cast off into the surrounding fluid. These free antibodies have the power of combining with antigen.

Antibodies then are the reaction substances which are formed in the body as the result of the presence of certain substances. They may be produced by the injection of antigen, i.e., bacteria, various microbic derivatives, red corpuscles, and other cells, as well as serum. Antibodies include antitoxins, antiferments, agglutinins, precipitins, and amboceptors or immune-bodies, opsonins, and other substances. Specific antibodies, produced by the parenteral introduction of foreign cells, bacteria or their derivatives, are called antibodies of amboceptor type or amboceptor. They are of the nature of the bacteriolysins and require the help of alexin or complement to complete the solvent action on these substances. "Amboceptor" means that this element possesses an affinity both for corpuscles and for complement. The term "complement" is so named because it completes the action of the amboceptor. R. Pfeiffer was the first to show that when cholera germs are placed in the peritoneal cavity of a guinea-pig immunized to cholera, or into that of a normal animal, if immune serum be also injected, there was globular transformation, loss of staining reaction, and finally complete disappearance of the cholera vibrios. This is the so-called *Pfeiffer's phenomenon*. Here was produced in the body of the guinea-pig a substance—antibody—which reacted specifically to its antigen—cholera vibrios—with the result of the destruction of the antigen. Before long similar observations were made with respect to typhoid fever, pest, and other bacteria, under similar conditions, which resulted in bacteriolysis in general.

Bordet showed that the laws which govern bacteriolysis by means of immune sera were apparently identical with those governing Pfeiffer's phenomenon. He also showed that the essential facts could be reproduced exactly if red corpuscles were substituted for bacteria. He showed that guinea-pig serum has normally no action on the red corpuscles of the rabbit, but it becomes hemolytic to the latter after a few injections of rabbit's blood, just as an animal which was formerly destitute of that power became able to dissolve the cholera vibrios (in Pfeiffer's phenomenon) after a few injections of that organism. This discovery of acquired hemolytic powers, arising from the injection of foreign red corpuscles, proved the starting-point of a most interesting series of researches, for it was soon shown that the phenomenon was not an isolated one, but that it might be produced when almost any animal cell took the place of the red corpuscles. Collectively we now term all these antibodies of amboceptor type which are specifically directed against animal or vegetable cells, cytolysins or cytotoxins, and we designate the individual members of this order according to the cell against which their action is directed (according to the type of the corresponding antigen) and thus distinguish between erythrocytolysin (hemolysin), leucocytolysin (leucolysin), neurolysin, nephrolysin, etc. The bacteriolysin would thus merely represent a species of cytolysin.

*Read in the Symposium on the Wassermann Reaction at the meeting of the Rochester Academy of Medicine, December 10, 1913.

The discovery of a third substance, alexin or complement, by Buchner, Nuttall and others occurred as a result of the controversy between Metchnikoff and the humoralistic school, in the interpretation of many phenomena concerned in im-

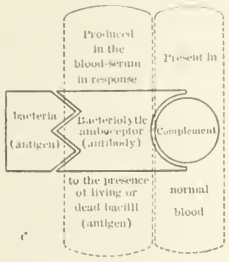

Fig. 1.—Bacteriolysis system; result, bacteriolysis.

munity. The result of this controversy proved that the circulating blood had the power of killing certain bacteria and that this property was even more marked in the serum. By injecting an antigen consisting of bacteria, cells, etc., there is produced in the blood serum of that animal, antibodies which cause their antigens, for which they are specific, to collect into clumps or masses. These antibodies are called agglutinins and the process agglutination. This effect is best seen after the addition of the serum of a convalescent typhoid fever patient (or of an animal which has been injected with typhoid bacilli) to a living culture of the organism. The bacilli soon lose their motility and gradually move nearer and nearer to one another, until they come into close contact. This process is well known as the Widal reaction and attained its greatest importance in the diagnosis of infections caused by typhoid, paratyphoid and colon bacilli. This same effect can be seen with the naked eye when emulsions are made with the serum and bacilli. In a few minutes this turbid fluid becomes clear and all the organisms will be found to have collected into a single mass or a few masses at the bottom of the test-tube. Microscopic examination will show that these organisms do not lie horizontally side by side, as one might expect in ordinary sedimentation, but point indifferently in all directions as if forcibly drawn together. Agglutination will occur almost equally as well when dead bacilli are used instead of living ones. The clinical diagnosis of cholera by means of cultures from the stools is carried out in the same way.

Now, if red corpuscles be used instead of the bacteria they will also clump at the bottom of the test-tube, the fluid portion of the tube becoming clear. An examination of the masses will show that (as in the case of the typhoid agglutination) the cells do not lie in the ordinary rouleux of shed blood, but lie without any trace of definite arrangement. Sometimes when the reaction is strong the cells actually fuse into a solid mass.

A phenomenon closely allied to the phenomenon of agglutination is that of precipitation. In exactly the same way as in agglutination proteids in solution, when injected into suitable animals, bring about the formation of another class of antibodies, which possess the power of clumping the molecules of the proteid in the solution similar to that proteid which was injected. After the addition of the clear anti-serum to the clear proteid solution, the mixture becomes opalescent, and then opaque, and after a time a precipitate is cast down. Hence these substances are called precipitins (a specific type of antibody). The substances with which they form a precipitate, and which call them into existence, when injected into a suitable animal, are the antigen. Bacterio-precipitins may be prepared by the injection of cultures of the bacteria, or the filtrates from old cultures. It is evident that they are antibodies to the substance in solution.

By injecting an antigen consisting of bacteria into the body of an animal, there also develops in the blood serum of that animal a bacteriolytic antibody of the amboceptor type. This amboceptor, in the presence of complement, has the power of destroying the bacteria used as antigen. As an illustration we may use as antigen a culture of *B. typhosus;* the serum of a convalescent typhoid fever patient (or of an animal which has been previously injected with *B. typhosus*), in which has been formed a bacteriolytic amboceptor; and for complement fresh guinea-pig serum. If these three substances are mixed in a test-tube at a proper temperature they will unite, and the bacilli will be dissolved. The combination of all three substances is necessary and together constitutes the "bacteriolysis system." This system is identical with the "hemolysis system" except that in the latter system there is present an indicator (hemoglobin) which shows by color changes whether or not the corpuscles are dissolved. The following diagram represents in an elemental way the combination of the three substances in the "bacteriolysis system."

Hemolysis means the ability of the serum of one species of animal to dissolve the blood corpuscles of another species. This power can be greatly increased by injecting several times the corpuscles of a sheep into a rabbit. As a result of introducing the sheep's corpuscles (antigen) there forms in the rabbit's blood a hemolytic amboceptor (antibody). To complete the action of amboceptor a third substances is needed and this is present in all normal fresh blood-sera. Occasionally a serum is found that contains amboceptors for a certain kind of cell, but not any suitable complement. The complement necessary to complete the action of the amboceptor may then be found in some other animal. If the fresh serum of a rabbit thus immunized against sheep is placed in a test-tube and sheep's corpuscles added, the amboceptor which has

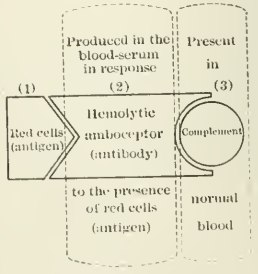

Fig. 2.—Hemolysis system; result, hemolysis.

formed in the rabbit's blood unites with the complement already present and with sheep's corpuscles, dissolving the latter. Hemolysis is indicated by the change from an opaque or cloudy, to a clear or transparent red color. All three sub-

stances—a hemolytic system—(1) corpuscles, (2) hemolytic amboceptor, and (3) complement must be present or hemolysis does not occur. A similar diagram may be used to represent this system.

A practical application of hemolysis has been its use in the medicolegal identification of blood-stain. As the legal question at issue is usually whether or not a certain blood-stain is of human origin, it is ordinarily only necessary to examine the material in question in reference to its behavior toward an antihuman serum. If, on the other hand, the antihuman investigation has shown that the material was not of human origin and it is desired to ascertain from what animal species the blood was derived, corresponding sera must, of course, also be available.

Lytic sera owe their power to the conjoint action of complement and amboceptor. Under certain circumstances when amboceptors are present in excess the complementophile groups of the amboceptors may unite with the complement to such an extent that lysis is markedly diminished, if not suspended entirely, because of lack of complement for the amboceptors that have become attached to the cells. The disappearance of free complement in a mixture of antigen and antibody (Bordet-Gengou phenomenon) is often spoken of as "fixation of complement." It was at first thought that the amboceptor modifies in some way the cells, so that they are rendered susceptible to the action of the complement, which was thought not to unite with the amboceptor. This does not harmonize with the later discoveries that complement could be deviated. The discovery that complement could be bound led to the use of an excess of amboceptor and to the combination of this system with the hemolytic system. If in the first system the complement has been bound, then there is no complement present to complete the action of the hemolytic amboceptor and hemolysis cannot occur. This indirect way of determining the presence of antibody or antigen has been applied to infectious diseases, cancer and especially to syphilis. It has found its widest field of practical application in the diagnosis of syphilis, in the form of the Wassermann reaction, but there is reason for thinking that this same principle of complement-fixation may reach an equal degree of usefulness in the diagnosis of latent gonococcus infection. At present excellent results have been reported from different sources. This discovery, then, of complement-fixation has opened up a great field for investigation into the presence of antibodies in the body fluids by this method. Researches with regard to the opsonic and bacteriolytic action of the serum of syphilitics have been rendered very difficult because of the great difficulty in obtaining pure cultures of the *Treponema pallidum*. This fact has led Wassermann and others to study the serum of syphilitics in this indirect way by means of the deviation of complement.

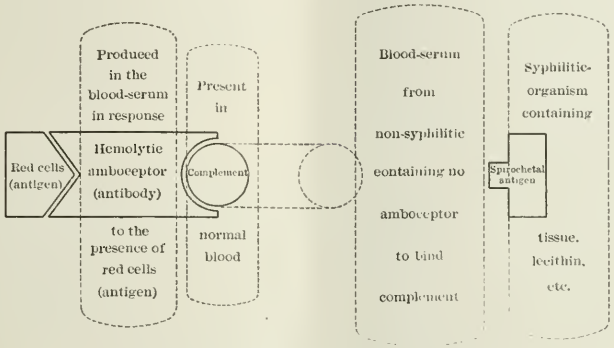

FIG. 3.—Hemolysis: negative Wassermann reaction.

When reaction products of amboceptor character are brought together with their corresponding antigens in the presence of complement, an interaction takes place between the first two mentioned bodies, in consequence of which complement is bound. Wassermann had this idea in mind when first he applied the complement-fixation to the study of syphilitic patients. His idea was that antibodies of amboceptor character might be present in the blood-serum of such individuals, in which case it should be possible to demonstrate them to-

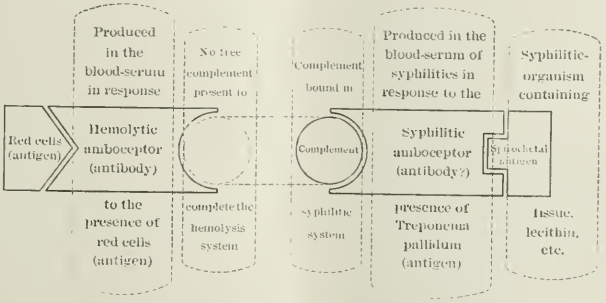

FIG. 4.—No hemolysis; positive Wassermann reaction.

gether with spirochetal antigen on the one hand and complement on the other. The complement would be bound to a greater or less extent as the result of the interaction between the other two factors. Then, by adding washed red corpuscles and a corresponding hemolytic amboceptor, hemolysis would, either not occur at all, or do so only to a limited extent, according to the degree to which the available quantity of complement had been bound. The exact outcome of this reaction depends, of course, upon the quantitative conditions.

Since the cultivation of the syphilitic spirochete had at that time not been accomplished, Wassermann was obliged to make use of extracts of organs which were rich in the organisms in question. Later work showed that a lipoid (fat-resembling) substance, lecithin, was able to combine with the syphilitic antibodies, and is now used instead of an extract of syphilitic organism-containing tissue. The most recent investigations appear to prove that the Wassermann reaction is not necessarily a true antigen-antibody reaction, according to the ordinary Bordet-Gengou phenomenon, but may be produced by certain lipotrophic substances formed in the tissues of syphilitics during the progress of the disease. The exact method is still unknown, we know merely this: that complement in the presence of syphilitic antigen may be rendered inactive by one or more substances in the body fluids of a syphilitic or parasyphilitic patient. Numerous modifications of the Wassermann method have been proposed, but the original method still remains the most reliable.

The Wassermann reaction is now generally accepted as the most valuable aid we have in the diagnosis of syphilis and in the control of treatment. It must rank as one of the most important discoveries in the history of medicine, and in its absence the triumphs of Ehrlich's salvarsan could never have been achieved. Its employment forms the basis of the modern treatment of syphilis, and serves as the most delicate indicator of the resultant changes which lead to the recovery of the patient, besides being the most delicate method that we possess for the diagnosis of latent syphilitic lesions.

Since its introduction no biological test has been so universally abused as the Wassermann, especially when the laboratory worker failed to confirm the clinician's diagnosis. This is more manifest since we know that the reaction is lipoidal in nature, and not a true antibody test. More especially since the advent of salvarsan, as a positive reaction may change to a negative and reverse in a relatively short time. Positive results have been reported from time to time in diseases other than syphilis but with improved technic the number is growing smaller.

The Wassermann reaction is dependent for its results on the skill and knowledge of the serologist. The results of the test depend, in a great measure, on the absolutely perfect standardization of the reagents used; these are subject to variations in the hands of different serologists. As a result of these differences, diversity in results is not infrequent. The test should be made only in properly equipped laboratories by those who have received special instruction and who devote a large part of their time to this work. Under such conditions results will be satisfactory, but the interpretation of the test must always remain with the clinician. The laboratory report deals only with the result of the test—that there was complement-fixation with the serum used in the test—and it should rest with the clinician to correlate this result with the clinical condition present.

## THE INTENSIVE TREATMENT OF SYPHILIS OF THE NERVOUS SYSTEM BY NEO-SALVARSAN, INTRAVENOUSLY, AND MERCURY BY INUNCTION.*

By J. W. STEPHENSON, M.D.,

NEW YORK.

CHIEF OF CLINIC, SECOND DIVISION, NEUROLOGICAL INSTITUTE.

The therapy of salvarsan and neosalvarsan may yet be said to be in an experimental stage, and in no branch of medicine is this statement truer than syphilis of the nervous system. Much has been written relative to the efficacy of the two preparations, but as yet the workers do not agree as to which preparation or method of administration yields the best results.

Good results may be said to have accrued from all the various methods, etc., but as yet none of us can claim the goal we seek—that of ultimate results. We can only live in expectancy, basing our optimism upon the concomitant, clinical, and serological results following the individual methods adopted. Of these results but one can be considered a criterion, viz., serology, and the one factor in this which we must primarily combat is the manifestation of living *Treponema pallidum*, represented, serologically, by the positive Wassermann reaction. Pleocytosis, *per se*, is but the exudative manifestation of the active Treponema. The living Treponema remaining, in dormant or active state, must be eliminated; otherwise, though the pleocytosis be overcome and our patient clinically well, the presence of the living Treponema, represented by the positive Wassermann reaction, keeps our patient in imminent danger—active manifestations of which may come upon him as the thief in the night. It is because of the gratifying results following the intensive method of treatment, as adopted on the Second Division of the Neurological Institute, that I ask your indulgence while giving a report covering fifteen cases.

Time will not permit of a full discussion of the theory of the method, but I might mention the assumed principle is the cumulative effect of the drug, *i.e.* before the activity of the drug is lessened by excretion, more is administered, and in this way the patient, by a process of gradual establishment of tolerance, becomes saturated with the drug in such a manner that the usual untoward effects of same are avoided.

The method adopted is as follows: 0.45 grains neosalvarsan is administered intravenously every third day (*i.e.* given a Monday, repeated the following Thursday, two days intervening) for five injections. In paresis, taboparesis, and other actively severe infections, this is supplemented by inunctions of mercury (40 to 60 grains) the days the patient does not receive the injection.

Many, and in fact the majority of unfortunate sequelæ of neosalvarsan administration are attributable, in the writer's opinion, to faulty preparation or administration of the drug. We consider 75 c.c too concentrated a solution of 0.45 grains and invariably use from 90 to 100 c.c. Freshly distilled

*Read before the New York Neurological Society, January 6, 1914.

water is boiled at least five minutes and then cooled to room temperature by running water. The apparatus used is the ordinary gravity one. The method of administration is as follows: 30 c.c. of lukewarm, previously sterilized, decinormal saline is introduced and as this escapes from the container the neosalvarsan solution is poured in, and as the last portion leaves the container 30 c.c. of lukewarm decinormal saline is again introduced. Especial care is taken that as small amount as possible of the neosalvarsan solution comes in contact with the warm saline, lest the warmth of the saline increase the toxicity of the drug.

Between thirty-five and forty cases have been treated after this method. We have had no alarming sequelæ of the first series. Of the five patients given further injections, one, to whom the second series of injections was given at irregular intervals, died twenty-nine days after the last injection, details of which will follow.

The immediate effect, or so-called reaction, following the series of five have been as follows: It is the usual course with tabetics that the pains are much worse from 24 to 36 hours after the first injection. After the second there may be a slight exaggeration, after the third none. In a very small number chill and slight rise of temperature have followed the first injection only. As yet there has been no case of diarrhea.

In the large majority of cases a slight conjunctival icterus has appeared after the third injection, but has been only of a few days duration. In those cases supplemented by mercury the patient usually expresses himself as feeling "very weak" after the fourth injection, but this I attribute to the mercury, as the patients who receive no mercury never so express themselves.

One case developed a skin Herxheimer after each injection. One case developed a mild arsenical dermatitis. One case developed a herpes zoster two weeks after last injection. In paresis the mental condition is usually more pronounced following the first injection, but not so affected by subsequent ones.

Case I.—Mr. T., single, age 49 years, entered institute April 13, 1913. Patient himself unable to give any account of illness. A friend stated it began eight months previous with difficulty in walking which progressed rapidly until he was bedridden. Soon thereafter speech became affected and this also progressed rapidly. He is unable to stand alone, speech unintelligible, marked mental confusion. Examination reveals Argyle-Robertson pupils, absent knee and ankle jerks, gross pedal ataxia; distended bladder, necessitating catheterizations. Serology: serum Wassermann, positive; spinal fluid Wassermann, positive, 89 cells per c.m., globulin excess, Fehling reduced. Diagnosis, taboparesis. April 30, 1913, series with mercury, 60 grains. Patient began to improve after the third injection and progressed rapidly until within three weeks after beginning of series; he was walking without assistance, speech fairly clear, no urinary difficulties, slight confusion only. Serology: May 13, 1913: Serum Wassermann, negative; spinal fluid Wassermann, negative, 26 cells per c.mm., no excess of globulin, Fehling reduced. Discharged May 13, 1913; has reported regularly since and to the casual observer a normal man. This patient developed a herpes zoster two weeks after last injection.

Case II.—Mr. K., age 40 years, married, denies specific infection. One child died at four weeks; wife one miscarriage. Entered institute March 20, 1913, complaining of shooting pains in head for one week, disturbing sleep. Shooting pains in legs ten years; weakness of legs on walking long distances. Examination revealed Argyle-Robertson pupils, absent knee and ankle jerks, slight pedal ataxia, Romberg. Diagnosis: Tabes. Serology: Serum Wassermann, positive; spinal fluid Wassermann, positive, 77 cells per c.mm., excess globulin, Fehling reduced. Patient was given a series of three injections with mercury, 40 grains. His pain in head was immediately relieved. Within three weeks he began to have shooting pains in legs and on April 16 returned for serological investigation, which showed a negative serology *in toto*. However, he was given three more injections without mercury; reports three months later pains much relieved.

Case III.—Mr. F., single, aged 28 years, specific infection 1902; treated actively with mercury and iodides. For the past six months he has had attacks of severe urethral and rectal pain with occasional vomiting. Pain described as boring, burning pain, beginning in rectum and gradually extending over perineum to penis, occurring daily many times and requiring opium suppositories to relieve. He had been given three injections of salvarsan at intervals of two to three weeks with mercury with no relief; entered institute December 30, 1912; examination negative, except for Argyle-Robertson pupils and segmental anesthesia. Diagnosis: Tabes. Serology: Negative except serum Wassermann, positive (most probably his previous treatment had rendered negative the spinal fluid). He was given the series without mercury. He had a bad crisis after the first injection, a slight one after the second and third, but since the fourth he has had none. He has reported regularly during the past four months; no crisis. The Wassermann remained positive after the series. He was given a second series of four; Wassermann still remained positive. This patient developed a skin Herxheimer after each injection.

Case IV.—This patient, a woman, age 35, was a case of tabes of eight years' duration, having severe intercostal crises, never passing through a menstruation without agonizing pains. She had been given three doses of salvarsan and other antispecific treatment with no relief. Entered institute March 25, 1913, for possible root section. Owoing to inability to locate definite segmental distribution this was abandoned and a series of three injections as given in the five (no mercury) were administered. Serology befores series: Serum Wassermann, positive; spinal fluid Wassermann, positive, 15 cells per c.mm., globulin negative, Fehling reduced. Serum Wassermann persisted after the three and a series of four injections were given. We have been unable to get a serological status since. However, she was known to pass through four menstruations without pain and as she stated she would return if she had any pain we assume she is now eight months free of crises.

Cases three and four are cited to show clinical results obtained with neosalvarsan, where salvarsan failed.

Case V.—Mr. S., age 40 years, single, contracted syphilis September, 1912; treated by mercury and iodides. In January, 1913, began to have headaches, which persisted in frequency and intensity. During March of the same year began to have spells of temporary speech defect, nature of which from history suggests sensory aphasia. Still later, that is, about one month, before entering institute, he would have "visions" appearing before him. His friends began to notice that he was getting "stupid." Three days before entering institute it was noticed he had some difficulty in walking—would wabble. He had had an occasional vomiting spell. Entered institute August 4, 1913. He was in a state of marked mental confusion, walked only with assistance, complained of severe pain in head and back of neck. His mental condition was such that he made a poor witness. Physical examination revealed sluggish pupils, equal in size. A questionable intention tremor of right upper extremity and also questionable increased flexes on the right. The plantar responses were flexor—the left active, the right slow; no Oppenheim nor Gordon. There was slight neck rigidity. Fundus examination disclosed swelling of disc, approximately 3½ diopters left, 2½ diopters right. Serology: Serum Wassermann, positive; spinal fluids Wassermann, positive; 93 cells per c.mm., excess of globulin, Fehling reduced. Diagnosis: Luetic meningitis with left frontal gumma encroaching upon left temperosphenoidal. He was given the series with mercury. Patient was kept constantly under observation for probable operative interference. During the first week he was a very ill man, but improvement began the second and he progressed rapidly until within three weeks after last injection he was clinically well; no headache or confusion and walking well. Serology

five weeks after beginning of series: Serum Wassermann, negative; spinal fluid Wassermann, negative; 48 cells per c.mm., no excess of globulin, Fehling reduced. On account of the pleocytosis he was given three more injections at the same intervals. This man has continued to do well and is now in active duty in the fire department of one of our large cities, being recently advanced to captain. Eye report on leaving hospital: "Practically no elevation of disc."—Dr. Holden.

Case VI.—Mr. M., age 41 years, married; one child born dead; admits syphilis when "quite young" and received the "usual treatment." Entered institute July 26, 1913. Story given by wife was that during the latter part of the previous May he began to have "cramps with vomiting," which persisted in frequency and intensity. He had changed in disposition, being now very irritable and "hard to manage." He was in a state of marked mental confusion, irritable, talking incessantly, complaining of "cramps." These "cramps" occurred quite frequently, disturbing sleep, and requiring opiates to relieve. His speech was slurring and difficult to comprehend. Physical examination revealed Romberg, absent knee and ankle jerks; small irregular pupils, no light response, sluggish accommodation response; distinct tremor of facial muscles and tongue. Diagnosis: Tabo paresis. Serology: Serum Wassermann, positive; spinal fluid Wassermann, positive; 170 cells, per c.mm., globulin excess, Fehling reduced. He was given the series with mercury. Owing to his mental condition he had to be sent out of hospital, but returned the following day, so there was no break in the therapy. After the fourth injection he began to improve, his gastric crises becoming less frequent and severe until several days before he left hospital he had none. He became rather docile, though he had an occasional spell of irritability. His speech became readily intelligible, but distinctly slurring. Serology four weeks after entering: Serum Wassermann, negative; spinal fluid Wassermann, negative; 16 cells per c.mm., no excess of globulin, Fehling reduced. Report three months after leaving hospital, no pain, but continues to have spells of irritability and incessant talking.

Case VII.—This was a case of tabes having, for the past eight months, daily crises of severe intercostal pain. He had been operated upon for gallstones, appendicitis, and gastric ulcer within the past two years; denied specific infection; wife never pregnant. Serology: Serum Wassermann, positive; spinal fluid Wassermann, positive; 34 cells per c.mm., globulin excess, Fehling reduced. He was given the series with mercury. Five weeks after beginning of series serology was serum Wasserman, negative; spinal fluid Wasserman, negative; 10 cells per c.mm., globulin negative. Lancinating character of pain was relieved for three months, but he had an occasional dull ache. The shooting pains then returned and he was given another series of three without mercury, which has afforded some relief, though he is not yet free.

Case VIII.—Mr. H., age 36 years, denies specific infection; no children. Entered institute September 2, 1913. Story by wife was that February prior he had been in one of the State hospitals on account of his mental condition. Had had two generalized convulsions. He was very restless, talking incessantly, memory poor. Complained of pedal paresthesiæ. Examination revealed absent knee and ankle jerks; slight tremor of tongue; pupils irregular, no light response, slow accommodation; test words fairly well performed. Diag-

A CONCISE SUMMARY OF RESULTS.

nosis: Tabo paresis. Serology: Serum Wassermann, positive; 27 cells per c.mm., globulin excess, Fehling reduced. He was given the series with mercury. Four weeks after beginning of series serology negative *in toto*. His condition slowly improved and four weeks after leaving hospital he returned to his former vocation—reporter for one of the leading city papers. He has been at work now five weeks.

Case IX.—This was a case of tabes in a man 45 years old, with shooting pains and gross pedal ataxia. Serology: Serum Wassermann, positive; spinal fluid Wassermann, negative; 127 cells per c.mm., globulin slight excess, Fehling reduced. He was given the series without mercury. Serology twenty-one days after entrance: Serum Wassermann, negative; spinal fluid Wassermann, negative; 40 cells per c.mm., globulin negative, Fehling reduced. No shooting pains since third injection, but an occasional dull ache in right heel; now three months.

Case X.—Mr. S., age 42 years, married; admits syphilis; complained of severe headaches and insomnia of nine months' duration. Recently, memory failing and speech defect noticeable; had had seven intramuscular injections of salvarsan. Entered institute September 17, 1913, in a state of mild mental confusion and somewhat irritable, very uncommunicative. Speech distinctly slurring and test phrases poorly performed. Absent knee and ankle jerks. Pupils irregular and no light response; feeble accommodation response; tremor of tongue. Serology: Serum Wassermann, positive; spinal fluid Wassermann, positive; 40 cells, globulin excess, Fehling reduced. Diagnosis: Tabo paresis. Series with mercury. Serology twenty-seven days from admission: Serum Wasserman, weakly positive; spinal fluid Wassermann, weakly positive; 11 cells per c.mm., globulin slight excess, Fehling reduced; his headaches relieved. Ten days later he was given another series of four without mercury and serology one week after last of the four showed negative serum and spinal fluid Wassermann, no globulin. Patient was very much improved; headaches relieved, no confusion. He is now doing slight duties around his store. This case is now two months standing.

Case XI.—Mr. B., age 39 years, married; admits syphilis ten years ago; actively treated. Entered institute September 30, 1913. Story by relatives was that for the past eight months he had been "nervous" and that there had been a "change in his speech." Patient was in a state of mild euphoria, talking with a decided slurring accent, and at times irrational. Examination revealed fixed pupils, knee and ankle jerks present, but difficulty to elicit; marked tremor of tongue; slight tremor of facial muscles; test phrases very poorly performed. Diagnosis: General paresis. Serology: Serum Wassermann, positive; spinal fluid Wassermann, positive; 34 cells per c.mm., excess of globulin, Fehling reduced. He was given the series with mercury and twenty-seven days after beginning of series serology was unaffected except pleocytosis reduced to 16 cells per c.mm. One week later he was given a second series of five. We have been unable to get a subsequent serology. He was discharged October 30, 1913; very quiet; talked rationally; no tremor.

Case XII.—Mr. F., age 34 years, married; no children; denies specific infection; periodic headaches of one year's standing. Since beginning of illness had given up society, previously being very fond of same; depressed with periods of irritability. Wife states his disposition had entirely changed. For five months a change in speech had been noticed; made unnecessary purchases. Entered institute January 11, 1913. Examination revealed marked tremor of tongue and facial muscles, marked speech defect, knee and ankle jerks active, plantars flexor; pupils small, irregular, and fixed. Diagnosis: General paresis. Serology: Serum Wassermann, positive; spinal fluid Wassermann, positive; 34 cells per c.mm., marked excess of globulin, Fehling reduced. January 15, 1913, a series without mercury was begun. Serology twenty-four days later unaffected except cell count 32 per c.mm. Patient was sent up the State and internal medication of tonic character, probably containing iodides, was instituted. For the first two weeks condition was reported worse, inasmuch as he was more depressed and irritable. Reports were then more favorable until in October the report was "he has, mentally, infinitely improved." During October he returned to New York. Serum Wassermann, still positive, but less so. Physical examination was as when first seen, but he was of a decidedly more cheerful disposition and his speech, except when excited, was fairly good. He was again entering into society, taking an active interest in the new dances. He was given another series of five with hypodermics of bichloride of mercury, grains 1/6, between the injections. Serology seven days after last injection: Serum Wassermann, negative; spinal fluid Wassermann, negative; 36 cells per c.mm., no excess of globulin, Fehling reduced.

Case XIII.—Mr. K., age 35 years, married; wife no pregnancies. Entered institute September 29, 1913; state of marked mental deterioration, grandiose ideas, unintelligible speech, filthy; no history obtainable from patient, but wife dated illness sixteen months, with gradual progression; examination revealed fixed and irregular pupils; active jerks; marked tremor of tongue and facial muscles. Diagnosis: General paresis. Serology: Serum Wassermann, positive; spinal fluid Wassermann, positive; 63 cells per c.mm., marked excess of globulin, Fehling reduced. He was given the series with mercury. Serology seven days after last injection unaffected except cell count reduced to 16. His mental condition was unaffected. If anything there was a slow progression. Ten days after last injection a second series was begun. After the second a slight rash appeared on the extensor surfaces of the arms, which disappeared within thirty-six hours. One week later he was given 0.25 grams and this repeated in five days. Within thirty-six hours he developed a pronounced rash over the entire body and four days after appearance of rash general edema appeared and progressed rapidly, causing closure of the eyes; blood and uranalysis reported negative. He was seen by an eminent dermatologist who pronounced it arsenical dermatitis. The temperature varied between 99.5° and 101° F. Under hot packs and other eliminative measures the edema disappeared within five days, leaving the skin scarlet red and of a "fish-scale" feel. Desquamation soon set in. Intense itching set in and, owing to mental condition, patient was hard to handle, and in spite of best efforts he got up a mixed infection as a result of his scratching and filthy habits. However, for a week he slowly improved and we felt encouraged only to be discouraged by a second appearance of the rash over the desquamated areas. His general condition soon began to show the effects of the drain; he began to refuse nourishment and have periodic attacks of vomiting of a projectile nature, and two days after onset of vomiting died. Daily uranalysis in this patient up to two days before his death were negative, when a trace of albumin was demonstrated. Nor was there any evidence of hepatic involvement. His condition was a skin one, and in my opinion had his mental condition been otherwise he would have survived, inasmuch as we would have had his cooperation. To the contrary, it was with force that the therapy was carried out. I do not think this death should be attributed solely to the neosalvarsan. It, of course, was contributory. Serology after last injections unaffected except cell count reduced to 8 cells per c.mm. and there was no excess of globulin.

Case XIV.—Mr. U., married, age 45 years; six children; denies specific infection. For ten years has been having spells of "mist before the eyes followed by intense headaches." These first appeared every two or three months, but progressed in frequency until they were recurring daily. In August, 1913, had an attack of numbness and deadness affecting the entire left side, which incapacitated him for twenty-four hours. Since then there has been a constant numbness in the side. Entered institute October 10, 1913. Examination revealed pupils little irregular and slow to light; knee-jerks lively; plantar responses flexor; no Romberg; no speech defect. There was a slight pallor of the temporal half of disk. Diagnosis: Cerebrospinal syphilis. Serology: Serum Wassermann, negative; spinal fluid Wassermann, positive; 124 cells per c.mm., excess of globulin, Fehling reduced. He was given the series with mercury. Six weeks after beginning of series patient had had only one attack of "mist before the eyes," and, unlike the previous attacks, was not followed by headache. The numbness persisted. Serology: Serum Wassermann, negative; spinal fluid Wassermann, negative; 11 cells per c.mm., no globulin, Fehling reduced.

Case XV.—This was a case of tabes of eight years' duration, having gross pedal ataxia and severe shooting pains, diplopia, and urinary precipitancy. Serology on admission: Serum Wassermann, positive; spinal fluid Wassermann, positive; 34 cells per c.mm., globulin excess, Fehling reduced. She was given a series of four (refused to take more). Serology five days after last

injection: Serum Wassermann, negative; spinal fluid Wassermann, negative; no globulin, Fehling reduced. Owing to an oversight the fluid was disposed of before counting. Reports three months after leaving institute no pain; walking quite well without assistance; no urinary precipitancy.

Summary of Results, Serological and Clinical, Following the Series.—The serological examinations were made from three to twenty-seven days following the last injection. It is this rapidity with which the serology is influenced and the concomitant clinical improvement to which I desire to call your special attention. And I might add the results herein reported are but examples of those obtained in the total number of cases treated by this method. Time required for the series, fifteen days.

Serological.—Of the fifteen cases the Wassermann was positive in the serum only in two cases. One remained positive. One rendered negative. The Wassermann was positive in the spinal fluid only in two cases. Both rendered negative. The Wassermann was positive in the serum and spinal fluid in eleven cases. One not subsequently examined. Of the ten examined six were rendered negative, one weakly positive, three unaffected. These four given a second series, the weakly positive became negative, one of the three unaffected became negative, one remained positive, one unable to get a subsequent serology.

Pleocytosis was present in thirteen. There was, with one exception, considerable reduction in all cases.

The protein test showed excess of globulin in twelve, one slight excess. Of the twelve showing excess, nine were rendered negative, three slight excess. The one slight excess was rendered negative. The presence of arsenic in the spinal fluid was demonstrated.

Clinical.—Of the fifteen cases, illness was such that thirteen could not pursue their usual vocations. Of the thirteen, improvement following the first series was such that eight returned to their work within six weeks to two months after beginning of therapy. Four showed slight improvement, one no improvement. The two remaining cases were considerably improved, one being relieved of shooting pains, the other dizzy spells much less frequent and not followed by headache.

*Conclusions.*—Serological: In exudative tabes and other active syphilitic involvement of the combined cerebrospinal system the serology is markedly influenced, if not rendered negative. In a small minority of the cases of tabes the Wassermann has remained positive. (Wassermann fast tabes, Kaplan.)

In general paresis we can only say the pleocytosis can be influenced. We have not had a sufficient number of cases to draw any definite conclusions. However, in the one case, recognized in its incipiency and treated personally by me, the results were such that I am of the opinion that even this scourge, recognized early, is not impregnable.

Clinical: In exudative tabes and other active syphilitic involvement of the combined cerebrospinal system we can give a decidedly hopeful prognosis.

In general paresis we must bear in mind the remissions occurring so frequently in these cases, therefore though we have reported two of the cases showing slight improvement, we must reserve definite conclusions until further time has elapsed. The one early case above referred to and not reported in this number has been for the past thirteen months a normal man. I wish to express my gratitude to Dr. Frederick Peterson for the privilege of instituting the therapy on the wards of the Institute, to Dr. Chas. L. Dana for the privilege of reporting two of his cases, and to Dr. D. M. Kaplan for the serological studies.

149 East Sixty-seventh Street.

## THE VALUE OF SMALL CLASSES.*

By EDWIN W. DWIGHT, M.D.,

New York.

Medical Director, New England Mutual Life Insurance Company.

When our President suggested that I should prepare a short paper for this meeting I chose as my subject "The Value of Small Classes" for the reasons that the subject interested me, and that I believe at the present time such a paper might be of value when we are all interested in the work of the Medico-Actuarial Committee.

In each volume a number of classes are treated with slight consideration on account of the small number of exposures. Actuaries believe in large figures. Their science is an exact one. Medical Directors of large companies are disposed, I think, to overestimate the necessity for large groups, possibly because such large groups are only available to the Medical Directors of large companies. Under these conditions it would not be surprising if some of the smaller companies were led to believe that as their classes are small, they are valueless; for even in the larger groups they can only furnish an experience, which in the minds of the Medico-Actuarial Committee, is not sufficient to develop facts. It would, I think be very unfortunate if as a result of our great investigation the smaller companies were impressed with the idea that individual investigations of their own experiences were not worth the doing.

Actuarial science is an exact science. Medical science is far from exact. Unquestionably the actuaries, working with definite and homogeneous groups, into which the element of personality does not enter, are right in assuming that the value of a group is in direct proportion to the numbers included in it. I think, however, that for our purposes there are few statements which are less true.

Medicine is not an exact science. Every medical problem is influenced or controlled by the personal element and there are no groups which are absolutely homogeneous.

There is no man among you who believes more thoroughly in investigations and statistics than I. There is no one who relies more in his daily work upon the results of such investigations and yet I feel that if we take statistics too seriously, and do not use ordinary human and medical intelligence in their interpretation, the use of statistics is associated with a good deal of danger and has very little value.

Facts are of the greatest possible importance. The best medical department is that which is controlled to the greatest extent by facts, but all statements are not facts even if supported by large groups of cases, and all of such statements, whether or not they are facts, must be interpreted intelligently.

A large number of small groups is of greater

*Read at the twenty-fourth annual meeting of the Association of Life Insurance Medical Directors, Philadelphia, October 29 and 30, 1913.

value than a single large one. You will learn more by subdividing your groups than you will by combining them. Homogeneity is more important than numbers, and with varying methods of selection homogeneity is impossible.

I was recently asked as to whether for my purpose I should prefer the individual experiences of ten companies or their experiences combined in one group. I was asked this question by a man thoroughly familiar with statistics and investigations and who is disposed to believe, as are all actuaries, that the larger the group the greater its value. I answered that there was no comparison, that to my mind the individual experiences were worth many times the collective experience. There are many reasons for this. One of them is that, in every collective experience the element of varying selection is introduced just as often as we introduce a new company, a new force or a new method.

In 1903 our company, appreciating to some extent the value of facts, took up an investigation of its own experience. There were very few to whom we could go for advice and we did the best we could with the ideas which we had and the material at our command. We felt that the first investigation should be as complete as it was possible to make it, that we should subdivide our classes to such an extent that we should, in so far as was practicable, find an answer to the problems which presented themselves to us or which might confront our successors.

The expense of such an investigation was of necessity great and we did not wish to do our work over again. Within a year we had some facts upon which we could base decisions. This investigation has never been completed and I hope never will be for new questions or modifications of old questions are constantly arising and the necessity for still further subdividing our classes is becoming more and more apparent.

So far we have investigated about 800 classes, being practically all of the single groups which were covered by our code. We have never had reason to regret examining any class. We have regretted a good many times that our code did not include other symbols and still further subdivisions. Some of these classes were absurdly small, so small that even I can see in them very little present value, but we have the code, we have the cards, and the material is constantly growing, so that, simply by the writing up of our new business, we shall be able to complete an investigation of these groups.

In the beginning we were cautious in basing our decisions on these small classes, but as our experience increased we became more and more impressed by their value and the remarkably slight variation between our results and the results of other investigations made on larger numbers by other men and on different material.

Sometimes our gross or general mortality differs considerably from the findings of other companies: part of this may be explained by selection and part in other ways, but almost without exception the general trend of mortalities and the general lesson to be learned is the same.

I have in mind two most admirable investigations carried on by Dr. Brandreth Symonds and reported at our meetings, one on Renal Colic and the other on Family Histories. In his paper on Renal Colic he bases his conclusions on 1,453 cases and shows a general mortality of 99 per cent., the results being rather worse in early life and again in late life. Our investigation of the same general subject was divided into two classes, one of 151 cases, the other of 336. Our mortality on the first group was 98.8: on the second 100.2. We also showed the same early and same late life mortality. Our general findings on family history agreed without exception with his; although our numbers were much smaller and our classifications quite different.

In comparing the results of our Company's investigations with those of the Medico-Actuarial Committee, so far as they have been published, I find that there are forty classes which are sufficiently near alike to justify comparison.

In these forty classes I do not find that the numbers involved have any relation to the variation in the findings, that variation is as great where we had 10,000 exposures as where there was less than 2,000. In several groups where our numbers are extremely small the variation is almost nothing, while in others where the groups are quite large the variation is a wide one. In almost all of these classes it is easy to explain the wide variation by differences in selection.

In the personal history of sugar, we had but 783 exposures to the M. A. of 17,454, the variation was but .02; with officers of steam vessels we had 1,992 and the M. A. 10,297 with a variation of .05; of painters we had over 6,000, M. A. 17,349, and a variation of 1.34. In these three classes the methods of selection were obviously about the same. We were all afraid of a history of sugar and during the period covered by this investigation we all selected them in about the same way. We all treated painters about alike as we did the masters and officers of steam vessels.

Our colored policy holders gave us 3,331 exposures with the M. A. 93,262 and a variation of but 4.41.

There were certain groups in which the New England contribution was very large in proportion to the amount of its business. It is, I think, undoubtedly a fact that we accepted these classes more freely than did the average company and our results show that we paid for that freedom.

We furnished 22 per cent. of the exposures with a history of blood spitting; our mortality was 16.8 above the M. A. Of acute articular rheumatism we had 42 per cent. with an increase of 18.65. With a history of asthma we had 35 per cent. and our mortality was 16.15 above the M. A.

In certain other classes the reasons for the variation are not so apparent. Why we should have had but 3 per cent. of the theatrical profession and had a mortality nearly three times that of the M. A., or why we should have suffered an increased mortality with druggists of 20.12 per cent., when we had but 3 per cent. of the total, I do not know.

I have made a number of tables in an attempt to satisfy myself as to whether the actual or relative size of a class had any relation to the variation in our findings, but I have not been able to demonstrate any such relation.

Having established the general mortality of any class we have but begun. The next step is to establish the general character or general trend of that mortality, and in this work our small and subdivided classes are of special value.

If the general mortality is very low it may not be worth while to spend much time in further investigation, but if it be high, or moderately high, further study is required. Refinements in general mortalities are not very serious matters, that is,

whether it be 90 or 110 per cent. of the American table may or may not be important, but the trend of that mortality and its character becomes worthy of serious study. Having found that a general mortality is high we must necessarily establish as to whether, like syphilis, tuberculosis, and certain occupations, it is high at all ages and in all insurance years, or as with light weights, a family history of tuberculosis and some Southern risks, it is high in early life and becomes good later, or like heavy weights, toxemia, and New York City business the high mortality is largely limited to late life.

For use in this connection our small, minute subdivisions and homogeneous classes become of the greatest possible value and from them we are able to learn many facts that are not apparent in a study of large undivided groups. While the variation in general mortalities may be very marked between small and large groups, dependent upon methods of selection, size of the classes and other factors, it is a fact that even with extremely small groups, no matter by whom and in what way they may have been selected, the general trend will be the same. This is to my mind a very much more important matter than is the simple question of average mortalities, and it is along these lines that the most helpful statistical work can be done. In this class of work I believe the smaller companies are in as good a position as are the larger and here is where the greatest development in medical selection will take place.

For the purpose of demonstrating that even very small classes may show accurately the character and trend of mortality, I have included charts showing the experience of our company with normal and heavy weights. These classes were subdivided by five percentages, but, in order to reduce the number of charts, only one-half of those are here shown, representing the experience of the New England Mutual Life between 1844 and 1905 with those of normal weight by Shepard's table and at 10, 20, 30, 40, 50, and 60 per cent. overweight. Those with normal weights, 19,096 cards with an exposure of 136,957, give an almost level curve showing the characteristics of both the light and heavy weight groups; that is, the slight increase in early life of the light weights and the increase in later life of the heavy weights. At 10 per cent., with 9,437 cards and 69,733 exposures, the light weight characteristic has disappeared and the chart is one typical of heavy weights, better than the average in early life, worse in late life, although the average mortality still remains good. With 20 per cent. overweight, cards 4,461, exposures 33,477, the curve is a little more erratic but still good in early life and bad in late life, the curve crossing that of the American experience somewhat earlier than with 10 per cent. overweight. With 30 per cent., a general mortality of 113.9, cards 1,521, exposures 11,164, we have a somewhat more erratic curve with the typical heavy weight characteristics. With 40 per cent. overweight, a mortality rapidly increasing, cards 356, exposures 2,762, a still more erratic but characteristic curve. Fifty per cent., still higher mortality, 85 cards, 743 exposures, an erratic curve but characteristic. With 60 per cent., an average mortality of 269.8, 56 cards, 415 exposures, the curve still erratic but the whole outline absolutely characteristic.

It would, of course, be absurd for us to accept these mortalities at each separate age as being absolutely accurate. At 20 per cent. and 30 per cent. it will be noted that we have at age 28 a higher mortality than at 23 or 33. I am not disposed to believe that there is at that definite age a serious danger which is not present five years before or five years after. A similar condition will be found in the 50 per cent. and 60 per cent. classes at ages 48 and 53. These are refinements which we cannot, of course, accept at their apparent or face value. It simply happens that in these groups there were more deaths at those particular ages and that the average of the three groups of five years would give us a much more accurate mortality curve.

The fact that a mortality curve is erratic does not mean that it is valueless, and if a little study be made of these seven charts I believe that the general mortality, its character and its trend, will be as well established from these small classes as it could be from others which might be many times as large. Each class should be studied with its predecessor and its successor and they will, I think, give us much more information than as if they had been less thoroughly subdivided.

It has been impossible for me to devote sufficient time to the preparation of this brief paper to demonstrate clearly to your minds the actual value of small classes. It would require weeks or months of time and many columns of figures. We have investigated about 800 classes varying in size from many thousands to a very few units, and the material with which these figures should be compared is almost without limit.

If you are each to be personally satisfied, as I am, with the value of these small classes, you must each be furnished with all of the facts and all of the experience which has come to us during this investigation. This it is obviously impossible for me to give. The best I can hope to do is to impress upon you that small classes have a value and that small homogeneous classes, properly interpreted and used, are of greater value than large ones of unknown or heterogeneous origin. I believe, in fact I know, that every company represented in this body has at its hand material, which, if properly handled, would enable it to control its mortality.

The best medical department is not that with the lowest mortality any more than it is that with the highest. The mortality which a company should have or should strive for is a purely executive and business question. To my mind, the best medical department is that which makes it possible for the company to control its mortality at a reasonable expense and with the smallest percentages of declinations.

I would not have you understand me as implying that a knowledge of facts by itself will control mortalities, but I know that without such a knowledge of facts it is impossible either to have or exercise such a control.

---

## A CASE OF ENDOPHLEBITIS OBLITERANS OF THE CENTRAL RETINAL VEIN WITH RESULTING ACUTE GLAUCOMA.

By DAVID WEBSTER, M.D.,

NEW YORK.

THE history of the following case presents several points of interest and seems worthy of being placed on record:

C. N. M., age 63, married, lawyer, came to me to be fitted with glasses on August 24, 1905. His eyes were normal with the exception of a low degree of hypermetropia with stigmatism. November 17, 1911.—His

eyes have bothered him lately. His vision has been blurred and his eyes have pained on use. He discovered this morning that he could see very little with his left eye. Ophthalmosopic examination showed that the loss of vision was caused by retinal hemorrhages of various sizes and shapes scattered throughout the left fundus, a typical picture of retinitis apoplectica. Dr. W. Van Valzah Hayes, to whom I referred the patient for examination as to his general condition, furnishes me with the following notes:

"November 18, 1911.—Mr. M, age 70, of a long-lived family, smokes ten or fifteen cigarettes and a pipe or cigar in the 24 hours, has been a free liver, drinks half a pint of whisky and a bottle and a half of claret or beer a day. At times slightly gouty, no indigestion worthy of mention, bowels regular, takes congress water or bicarbonate of soda occasionally. Has had frontal headache at intervals all his life. Passes water two or three times during the night. Mentally alert as ever. Ten or fifteen years ago was unconscious for two hours; found himself walking where he had not expected to go.

"Physical examination: Knee jerk present; no Romberg swaying; lungs clear; heart regular, good force, accentuated second sound. Stomach and bowels are distended with gas. There is very slight hepatoptosis. Systolic blood pressure 210 (Janeway's instrument), diastolic blood pressure 175. Blood 90 per cent. normal. Urine 1012, 1020, small amount of albumin. Indican moderate amount; sugar, a marked trace; phosphates, few hyaline casts, fragments of white blood cells, and trace of mucus." Dr. Hayes prescribed for him and regulated his diet and habits.

December 16.—Numerous hemorrhages and exudations in left retina. L. V. = 20/200 in lower part of field.

January 24, 1912.—One week ago the patient caught cold in his head and four days later he noticed a grayish haziness of vision of left eye. Last night he had a good deal of pain in the eyeball and temple; sees halos about lights. There is some conjunctival injection. The pupil is moderately dilated. There is tenderness on pressure and the tension is + 2. Opacity of the media makes it impossible to see the fundus. Dr. J. B. Emerson examined the eye in consultation. Eserine was instilled and half an hour later the pupil was contracted, but the vision was not improved. Eserine and hot water applications were prescribed.

January 25, 1912.—Pain more severe, sight worse, eyeball very red, and tension higher.

January 26.—Eyeball remains red, tension + 3. Vision, fingers at two feet; visual field contracted. Blood-pressure, which has been 225, is now 195. Chloroform was now administered and an iridectomy performed. The coloboma was of good size and no iris was left in angles of wound.

January 28.—Anterior chamber full of blood. The pain is relieved. Dr. Hayes finds the blood pressure higher than ever.

February 8.—Allowed to go home with tension still considerably plus. Sees shadows, but cannot count fingers.

February 11.—Pain and tension greater. Stopped eserine and gave morphine to relieve the pain.

February 12.—Readmitted to hospital. Tension + 3; hemorrhage in anterior chamber apparently coming through pupil; dionin in eye *ter in die;* pilocarpine sweats.

February 19.—The eye has got steadily worse; no perception of light. Pain only partly relieved by injections of morphine. Upon consultation it was decided to remove the eyeball, and an Allport's enucleation was done the same afternoon. The orbital cavity healed quickly and the patient returned home a few days after the operation. In about a couple of weeks he was wearing an artificial eye and doing business. About the first of June he went to his summer home at Lake Placid. I did not hear from him again until I heard of his death, which occurred on June 15, 1912. His physician writes: "Mr. M. came under my care June 3 and was then suffering from an attack of aphasia, due in my opinion to an embolus from the heart. This organ was acutely dilated, Mr. M. having been exercising too much, and showed decided evidences of an old endocarditis, the mitral and aortic valves being both evidently affected. I found a general arteriosclerosis and evidences of interstitial nephritis also. Mr. M. rallied for a few days, the cerebral symptoms clearing entirely and the heart responding to treatment. On or about the 8th he overdid again (he was a most difficult patient to handle) and the heart utterly broke in compensation. Coma developed gradually, partly of uremic origin and partly, I think, from cerebral blocking. He rallied under vigorous treatment aimed at the kidneys. His heart continued to dilate, however, and acute pulmonary edema terminated the scene. The case, as I saw it, was primarily one of general arteriosclerosis with chronic endocarditis and, of course, some kidney changes."

The eyeball was examined by the late Dr. E. L. Oatman, who reported as follows: "April 11, 1912.—Microscopic diagnosis. The central vein at the lamina cribrosa is nearly occluded by endophlebitis proliferans. The retinal vessels are degenerated and the retina contains extravasation of blood. The anterior chamber presents the changes of acute glaucoma."

24 East Forty-eighth Street.

## TREATMENT OF PULMONARY TUBERCULOSIS BY THE INDUCTION OF ARTIFICIAL PNEUMOTHORAX.

By JAMES S. FORD, M.D.,

GABRIELS, N. Y.

ASSISTANT HOUSE PHYSICIAN, SANATORIUM GABRIELS

THE treatment of pulmonary tuberculosis by means of artificial pneumothorax, although of recent date, has obtained a well-defined foothold as a therapeutic measure among those who are making the treatment of this disease their lifework. It is true that this mode of therapy is limited to carefully selected cases but the results in such instances have been nothing short of brilliant.

The idea of the production of an artificial pneumothorax did not arise in recent times, though the first report of cases so treated was made only twenty years ago. The first reference found in the literature to this mode of treatment is in 1825, when Carson of Edinburgh suggested that air be introduced into the pleural cavity for the collapse of tuberculous lungs containing cavities. The idea was denounced as impractical, and it is not likely that such treatment was made use of at that time. In 1885 Cayley reported a case which had been treated along the lines laid down by Carson, but the method was hardly successful, though in this case it controlled an intractable hemoptysis. As this was an open pneumothorax the pleural cavity soon became infected, with the subsequent death of the patient. Not until 1882 was there any progress made in this form of therapy and in that year Forlanini, an Italian clinician working at Pavia, suggested the filling of the pleural cavity with the innocuous nitrogen gas and in this way obtaining a compression of the lung. The suggestion, however, was not acted upon until six years later when Forlanini compressed the diseased lung in a case of unilateral phthisis. Nothing was heard of this until 1894, when he made his first reports which were particularly favorable ones. These, however, did not cause any excitement in the medical world and it is unlikely that any one save Forlanini and his pupils were making use of this method.

In 1898, independent of Forlanini's work, John B. Murphy of Chicago, in an address before the American Medical Association, advocated the compression of the diseased lung in certain cases of pulmonary tuberculosis. The idea was not looked upon at all with favor and in fact was severely criticized by the medical profession of this country. In 1899 Lemke, Murphy's associate, before the same association, gave a favorable report on 53 cases so treated but no further interest was aroused in the measure. Shortly after this Lemke died and the

method of treatment for the time being seemed to have fallen into disuse in this country. Brauer of Germany, in 1907, seeing the results that Forlanini was obtaining, decided to try artificial pneumothorax on his patients and in 1911, along with Spengler, reported upon 102 cases, in which they said a great many of these were favorably influenced though otherwise they would have been hopelessly doomed. In 1908 the treatment seemed to grow slowly but steadily in popularity and from that time on its use has become more and more widespread. At first the cases selected were only far advanced ones and the treatment was given simply as a matter of last resort. The field, however, has broadened somewhat, and now early acute cases and cases of persistent and intractable hemoptysis are receiving the benefit of this form of therapy.

*Apparatus.*—There are a number of different apparatuses used for the administration of the nitrogen gas, but it is my purpose to describe the one most commonly used in this country, namely the Robinson apparatus. This can be purchased for about $35 or be made for about $8 or $10. The apparatus consists of two 2,000 c.c. bottles graduated for each 25 or 50 c.c. One of these bottles, A, contains the gas, while B contains the displacing fluid. This may be any antiseptic solution, but the one frequently used is a 2 per cent. solution of pyrogallic acid. A long glass tube inserted through a rubber cork passes down to the bottom of bottle B for the siphonage of the displacing fluid and is connected to a similar tube in bottle A by means of rubber tubing in the middle of which is placed a stopcock that is turned off to prevent leakage when the apparatus is not in use. The gas flows from bottle A through a rubber tube connected with a metal one. (The latter is not absolutely essential, but if used is about 8 to 10 inches in length.) Attached to this metal feed pipe is a piece of rubber tubing 4 to 6 feet in length, the end of which slips over a collar on the injecting needle. At a distance of about six inches from bottle A is a stopcock which regulates the flow of gas. Just below this is a glass or metal T which connects the water manometer with the feeding pipe, while between the manometer and the feed pipe is a stopcock which regulates the oscillations of the water. The manometer, which is a U-shape glass tube, is really the most important part of the apparatus for the operator to understand. The oscillations of the fluid will show whether or not one has been able to get into the pleural cavity, success in this way being evidenced by the recording of a marked negative pressure. Failure to get into an open pleural space, or the fact that one has penetrated the needle into the lung or into a blood vessel will be shown by an absence of the movements of the fluid. No gas should be turned on until a definite negative pressure has been obtained. The pressure is obtained from the readings of a scale which is marked up in cubic centimeters. A neutral point has been determined on this scale and all movements of the water above this are recorded as positive and those below as negative. The scale may be made of metal or a paper strip on a background as described by Lawrason Brown. It must be understood that these readings are relative rather than absolute. A bulbous enlargement put before the termination of the feed pipe may be recommended in order to catch any water that may come over from the manometer. For the first injection a specially designed blunt needle of the Robinson and Floyd type should be used, but later on for the refills an ordinary aspirating needle will answer the purpose.

For the refilling of bottle A the gas is obtained from a cylinder and passed through three wash bottles, one containing a solution of bichloride of mercury, the second sulphuric acid, and the last a 2 per cent. solution of pyrogallic acid. This removes whatever impurities may have been present in the gas.

*Mode of Procedure and Dosage.*—Having determined the most resonant area over the diseased lung, this site is selected for the injection. It is best at the beginning to administer ¼ grain of morphine and 1/150 grain of atropine to quiet the nervousness and fears that may be present in the invalid. The patient is placed on his good side in bed with a piliow so placed under him as to widen the intercostal spaces. The area chosen is then painted with tincture of iodine following which the skin is anesthetized with a ½ to 2 per cent. solution of cocaine or with novocaine and adrenalin solution. After the skin has been so treated, the needle is withdrawn and introduced at right angles to the body. It is slowly pushed inward, each layer of the chest wall being anesthetized, down to and including the pleura. The skin is then pinched up between the thumb and forefinger, incised with a tenotome and the blunt needle is pushed slowly through into the pleural space. This is known as Forlanini's method and if carefully followed no accidents should result. Brauer of Germany advocates dissecting down to the pleura and thus observe the condition of it and the underlying lung. If the latter is seen to move freely and the pleura is glistening a blunt trocar is inserted into the chest cavity. The method necessitates the sewing up of the different layers later and the risk of infection is great. Having learned from the negative pressure reading of the manometer that the needle has found a free pleural space, the gas is allowed to run in slowly. The flow of gas should be shut off frequently so that manometer readings may be taken and as the readings approach the neutral point great care must be taken as one can now easily get into danger.

For the initial dose 200 to 500 c.c. should be sufficient, but this cannot be made an absolute rule. As the gas is being given to overcome some symptom the accomplishment of this must be the guiding factor for the determination of the amount. The chest should be refilled in three to ten days, for if allowed to go much longer, all the gas from the initial injection will have been absorbed and such dense adhesions will have formed as to entirely obliterate the former free space. There are many who advocate the giving of small amounts and refilling frequently, and this seems to be the most rational method of procedure. Some observers declare against having a positive pressure or at least only a slight one, while others favor a positive pressure of 5 to 10 c.m. or even more at the end of the treatment. Here, as in the amount of gas to be injected, the relief of the symptoms must determine the amount of the pressure.

*Indications.*—The ideal case for the induction of artificial pneumothorax is a patient having one side diseased and progressive, febrile or afebrile, with or without cavity formation and an opposite healthy side. It is fair to say that this condition but rarely appears. (1) The cases that usually come for this form of treatment are those with a badly diseased one side and with the other involved to a great or

less extent. Some claim that an involvement of less than one-third of the good side should not be a contraindication. It frequently follows after the compression of the badly diseased lung that the other one, if not too extensively involved, will show a marked improvement, though it is now doing the work for both. The explanation for this is that the liberation of toxins into the circulation has now been checked and consequently the other side, no longer bathed in these, receives a chance to repair itself. (2) Intractable and persistent hemoptysis yields at once to compression treatment. Certainty must be had at first as to which side the bleeding is coming from or the result, as is obvious, will be disastrous. One who has seen the results of such treatment for this symptom can never doubt the efficacy of it. One patient who had bled copiously and often for more than 48 hours and lost over sixty ounces of blood, had no further trouble after the first treatment. Another patient who had bled at freqnently recurring intervals and in whom the periods between the hemorrhages were becoming lessened and the amount of blood lost each time greater, was up and around one month after receiving the pneumothorax, and had no further trouble from the compressed side. (3) Persistent fever from one side involvement that resists all other methods of treatment. There may be a marked rise of temperature following an injection, but this is due to the introduction of a large amount of tuberculin into the blood stream. This temperature drops to normal within twelve to twenty-four hours. (4) Artificial pneumothorax may be used in acute cases which seemed to be doomed to a speedy end within a short time. Even a partial compression in some of these cases seems to have a beneficial effect upon the morbid process. (5) Progressive afebrile cases may also be thus handled.

*Contraindications.*—(1) Cases with bilateral involvement and which are progressive, especially when the disease on the better side includes more than one-third of lung. (2) With firm adhesions of the diseased side. It is possible in some few of these cases to get into the pleural space and the pressure exerted by the gas may be great enough to break up these adhesions. It is possible when they are the cause of an incomplete compression that they may be broken up after a third or fourth injection due to the stretching and consequent weakening of these fibrous bands and a complete compression occur. (3) Uncompensated heart lesions. (4) Severe organic disease in other organs, as diabetes, nephritis, etc. Tuberculous enteritis as a complication to the pulmonary type does not strictly speaking constitute a contraindication, but no beneficial results have been seen in cases treated with gas where both have coexisted. Laryngeal tuberculosis is not a contraindication, for though the gas has no direct effect upon the laryngeal process, it indirectly produces benefit by diminishing the amount of irritating sputum that would pass over the lesion.

*Complications.*—(1) Pain. Patients in whom adhesions exist in the pleural cavity of the side compressed, may complain of sharp pain following the injection of the gas. This is due to the stretching of these adhesions and as the gas is absorbed with the consequent lessening of the traction the pain disappears. It is in such cases that the pressure exerted by the gas may frequently break up these fibrous bands. Provided too much gas has been introduced the patient will complain of a feeling of tightness but this disappears quickly with the absorption of the gas. It may, however, in some cases be necessary to suck out some of the nitrogen. (2) Emphysema: This is a more annoying than a dangerous complication. It may happen that due to the breaking of adhesions, gas may get into the mediastinum and work its way up along the trachea into the cellular tissues of the neck and face. No treatment as a rule is necessary as the gas is quickly absorbed. Another cause for this condition may be the gas escaping into the tissues along the tract of the needle. (3) Gas Embolism: Cases are on record where this has occurred and with a fatal termination. Careful attention to the readings of the manometer should remove practically all danger of this. If the operator will be sure not to inject gas until he has a marked negative pressure recorded he should be able to avoid this accident. One case is reported in which the embolism occurred at the third injection but the manometer showed a marked positive pressure. The autopsy findings in these cases are as a rule negative.

*Effusion.*—From the literature available on this subject, this occurs in from 45 to 75 per cent. of cases treated by the compression method. It may occur immediately following the first injection, or come on months after the treatment has been discontinued. It differs from the ordinary pleural effusion in that there is no tendency to be absorbed by the pleura. It must be aspirated and the longer it persists the thicker it becomes. The cause of this effusion has given rise at the present time to a great deal of discussion, but no view has as yet been put forth that is wholly satisfactory. Some of the reasons given are as follows: (1) Irritation of the pleura by the gas which at the time of injection is cold and the final pressure in the pleural space being too great. Even when the gas has been injected warm and a negative pressure has persisted, effusion has followed. (2) Cold weather causing a chilling of the chest with consequent inflammatory reaction on the part of the pleura. The effusion has occurred just as well in the heat of the summer as in the cold of winter. (3) A break in technique with resulting infection. In attempts to culture the fluid, no organisms save the tubercle bacilli have been found. Furthermore it seems unlikely that a fault in technique could occur in 50 to 75 per cent. of cases of many different workers. (4) It seems to occur frequently in patients who are in a much weakened condition following hemorrhage or a long siege of fever. (5) Normally the lung is full of hot flowing blood and tends to keep up the temperature of the pleura by its intimate relation with it. The compression of course destroys this relation and the pleura becomes chilled with a resulting inflammatory condition, thus giving rise to the effusion. Where effusion has occurred, it is necessary to draw off the fluid before the gas can again be given.

*Empyema.*—A secondary infecting organism as a streptococcus, pneumococcus, or influenza bacillus may become engrafted upon the effusion through the blood stream and this serves as an excellent culture medium with a resulting empyema. In this case surgical treatment must be availed of.

*"Pleural Eclampsia."*—It has frequently happened that some of the treated have suffered from marked syncope and this has come on just at the time the injecting needle pierced the pleura. Saugman has reported a case with a fatal termination. If the pleura has been anesthetized before the insertion of the needle into the free pleura space the

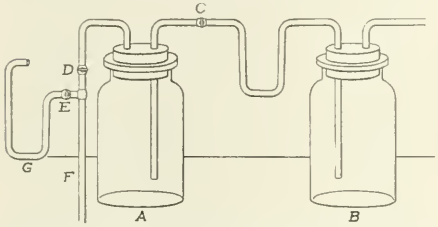
chances of this accident will be reduced to a minimum.

*Process lighting up in opposite lung.*—In cases with so-called deep or concealed lesions in the better lung it is possible that the compression treatment may light this up and cause a rapid extension of the tuberculosis on this side. The same may even occur, when there are signs of an arrested process in the good lung. Röntgenograms made of the case before treatment with a careful interpretation of the plate should go a great ways in helping to obviate the danger.

*Pneumonia in good lung.*—This has occurred a few times and is a very dangerous complication to treat. It usually results fatally for the patient and calls for the withdrawing of the gas.

*Infection of the pleural cavity due to faulty technique.*—Any violation of the rules governing asepsis may result in the introduction of pyogenic organisms into the pleural space with a consequent pyopneumothorax. The indications here of course are for surgical treatment, but the result is generally a fatal one.

One case of transient blindness has been reported, which was probably of reflex origin. Gas at the time was under high positive pressure.



Apparatus for the administration of nitrogen gas. A, bottle containing nitrogen; B, bottle containing displacing fluid; C, D, E, stopcocks; F, feed-pipe; G, water manometer.

*Incomplete compression.*—Adhesions in the pleural cavity may be the cause of an incomplete compression, the lung in some place being held to the chest wall. This often occurs at the base. Adhesions may be so scattered through the chest as to permit an hour glass contraction. Such cases are followed by a rise of temperature which persists, due to the locking up of the sputum below the neck of the contraction and with consequent greater absorption on the part of the patient. As soon as enough gas is absorbed to allow for the expansion of the contracted portion of the lung and a consequent release of the sputum the temperature at once falls to normal. Another condition to be met with is that due to marked adhesions throughout the chest, and though the gas may find its way in little or no compression results, but little gas pockets form themselves throughout the chest cavity. The only sure way to get knowledge of these results is by means of a Röntgenogram, and it is the opinion of the most capable men engaged in this work that such a procedure should always take place before and after the first injection. Information obtainable in no other way will be given by a careful study of these plates. Hemorrhage and indeed a fatal one has occurred from a partially collapsed lung.

*Results.*—As said above, the results of this form of treatment in carefully selected cases have been brilliant. It must, however, be recognized that the field at best is limited and it will never be much broader than at present. There is almost an instantaneous dimunition in the amount of expectoration, a rapid drop in the number of tubercle bacilli from the sputum, a quick fall of the temperature to normal or nearly so, and hemorrhage is at once arrested. Symptomatic cures are obtained in about 20 to 30 per cent. of the cases, though some writers have reported 40 to 45 per cent. of cases. When it is remembered that nearly all the cases reported on have been far advanced ones and were hopelessly doomed under the recognized form of treatment, the saving of 20 to 30 per cent. should be considered nothing short of marvelous. The percentage of cures from now on will undoubtedly be greater as the treatment will be given to earlier and more favorable cases. The age of the patient need hardly be considered in giving this form of therapy, as Pielsticker and Vogt have used it in young children and report marked success. They obtained excellent results in eight of ten cases, the children showing a wonderful improvement and a great tolerance to get along on one lung. Some of the cases so treated were regarded as utterly hopeless, but took a decided turn for the better following compression. The youngest case treated was ten months and the oldest fourteen years. It can now be safely said that after the compression treatment has ceased, the lung so treated does resume its normal functions to a greater or less extent, depending wholly upon the amount of disease present at the beginning of treatment. In a lung with cavity formation and a great deal of disease scattered through it, very little in the way of function can be expected from it when allowed to expand again. Some observers claim to have heard vesicular murmurs over the lung that had been compressed.

From an economic point of view the treatment is also a great success. Many of these patients are able to go back to work, so supporting themselves and family, having their refills done at the dispensary or physician's office. In this way, beds in hospitals and sanatori are provided for those cases who are in need of such treatment, and the cost to the community for the care of consumptives is reduced.

## ARTERIOSCLEROSIS AS THE ORTHOPEDIST VIEWS IT.

By SIGMUND EPSTEIN, M.D.,

NEW YORK.

ORTHOPEDIC CHIEF, GERMAN POLYCLINIC; ORTHOPEDIC ASSISTANT, MOUNT SINAI HOSPITAL DISPENSARY.

In writing on such a hackneyed subject as arteriosclerosis, I am not unmindful of the fact that laboratory research has advanced our knowledge of the pathology of the blood vessels to a greater extent than bedside observation. New instruments of great precision have shed light on phases of cardiac and vascular degeneration hitherto most perplexing. To these I can add a little in the way of clinical items that have been impressed upon me in the routine of orthopedic practice. The manner in which such impressions are received is apt to be different from the way in which the subject is approached by the internist, who regards the local manifestations of arteriosclerosis as the results of a generalized disease. The orthopedist's assistance is sought for the relief of symptoms localized in the extremities. These may be of a more or less disabling nature, and deserve your attention from a new viewpoint.

In the upper extremity the *neurologist* is more frequently consulted for painful conditions of a chronic nature, possibly on account of the greater number of nerve lesions underlying intractable arm and shoulder aches. In the lower extremity any painful condition soon leads to interference with locomotion, and the orthopedist is called in. A good percentage of the aching, halting adults brought to our attention seem to be afflicted with processes directly or indirectly traceable to arterial changes. The obscurity of the symptoms presented, and the solving of a differential diagnosis, have stimulated us to a careful survey of the circulation of legs and feet; for these are the cases brought to us with the phrase "there is nothing to be seen"—by him who has senses, but uses them not.

Arteriosclerosis is a condition of the flesh that we are all heir to, thanks to the rapid pace of city life, to keen competition, and to the American habit of overeating. It is striking to note, however, the prevalence of early cases of the disease in some of our newly made citizens from the Continent. At the Mount Sinai Dispensary we have ample opportunity for observing many men and women, between the ages of thirty and fifty, complaining of painful extremities. They declare that the arms are aching and sore, that there is numbness and tingling, in the arms and forearms, legs and feet. Although teetotallers and free from syphilitic taint, as a rule, the men are heavy smokers of paper cigarettes. A few showed evidences of lead-poisoning, while a small series occurred in furriers, accustomed to the handling of pelts dyed with some arsenical preparation. Careful questioning brought out the fact that most of the remainder work 12 hours a day, in poorly ventilated workshops, they eat inadequate amounts of food for lunch, while two hours or more are spent in the street-cars to and from their homes. Some find time to attend night school. The nervous system is not affected in our cases. The only physical signs are the early arcus senilis, and tenderness over the femoral and brachial vessels. The treatment that does most good seems to be rest, forbidding the tobacco, change of occupation in some cases, and cold spinal douches. Cathartics and the iodides are to be recommended. The social service worker who can furnish vacation trips at little or no cost to these patients is a veritable Good Samaritan. When older persons are considered—a type more common in private practice—the advanced disease with high tension is the rule—and we are called upon to treat cramp-like pains in the ball of the foot, especially under the metatarsal arch. There are attacks, resembling intermittent claudication, that alternate with attacks of angina pectoris. There is severe, burning pain in the toes, sometimes with blushing or blanching. A shoe with an "anterior heel," described by A. G. Cook, has benefited some of my cases, others derive comfort from a soft, felt pad, strapped under the middle of the ball of the foot. In case of severe, recurring attacks, and especially where there is much complaint of cramps in the calf, a two weeks' rest-cure has done wonders for some of my patients. Osler speaks of terrific attacks of knotting of the vessels of the calf, in old persons, requiring opium for relief. An *x*-ray picture demonstrates such vessels, as well defined, bony tubes. After the heart or kidneys have become insufficient, we are apt to be consulted for swelling of the legs, or for weakness; the orthopedist can be of little service, except to refer the patient to a general medical consultant, and to provide for bandage support such as the crepe bandage, and to order massage of the extremities.

At this period of life, arteriosclerosis is an important but little recognized factor in the production of ankylosis. For instance, on removing the dressings immobilizing a Colles' fracture, you find that the shoulder or the fingers, and perhaps, too, the wrist, are stiffened from a form of traumatic arthritis. This condition is little understood, and might form the text of a sermon on the evils of prolonged fixation in old people. The rôle that arterial degeneration plays in the senile atrophic form of arthritis deformans is to be noted. How many cases of deforming of the fingers and hands, by deposits like Heberden's nodes, are associated with hardening of the arteries? A number of my cases have been relieved of joint symptoms of disabling

nature, by rest, proper support, etc.—only to be overtaken within a year by grave symptoms of arterial or cardiac disease.

*Aneurysm.*—We have long been on the lookout for cases of aneurysm, and only encountered one. This was a popliteal sacculated mass that had recurred many years after ligation, in a syphilitic subject. The blood-vessels of the sole of the foot, exposed to the effects of much trauma, seem to be comparatively free from aneurysmal disease.

*Obliterating endarteritis.*—By far the most interesting group of arterial diseases in orthopedic clinics is the one most familiar under the caption of endarteritis obliterans. This type of vascular affection is notorious for the frequency with which it is misdiagnosed. I have seen about seventy cases, and at least one-half had been under treatment for totally different conditions. One patient sued his family physician for heavy damages when gangrene occurred. Endangitis can be considered of economic importance, when an early diagnosis of a mild case may be the means of delaying, perhaps for years, unfortunate permanent disability. Some authors reject the division into Raynaud's disease, erythromelalgia, thromboangiitis obliterans, senile arteritis, and scleroderma. It is possible that these are all manifestations of the same process. A study of their occurrence in the orthopedic room, however, seems to indicate that they are etiologically, widely separate.

*Raynaud's disease.* — Well-marked Raynaud's disease, with true symmetrical local syncope, followed by asphyxia and gangrene, I have seen twice in children's surgical wards, but it is rarely encountered in orthopedic clinics. A mild form is quite common in which there is either ischemia or evanescent passive hyperemia. There is an apparent family predisposition to this vaso-motor disturbance in the feet, hands, and nose; Raynaud mentioned fright and the menstrual period as contributing factors. Persons quite healthy in other respects suffer from tingling in the feet and toes, and throbbing, aching, pain in the ankles. Immersion of the feet in very cold or very hot water causes them to swell and become very blue. For the faulty mechanism of the vaso-motor centers we refer the patients to the general practitioner for appropriate dietetic, climatic and drug treatment. Locally, alcohol sponging, avoidance of hot foot baths are advised. Stockings should be woollen and shoes that are comfortable and soft should be worn. The prognosis is good.

*Thromboangiitis obliterans.*—Buerger defines this condition as a clinical and pathological entity characterized by thrombotic occlusion of arteries alone or arteries and veins, giving subjective manifestations, chief among which are pain and the peculiar symptoms of intermittent claudication, and presenting objective phenomena, the most important among which are redness in the dependent position of the limb, marked blanching in the elevated position, evidence of arterial occlusion in the form of pulseless vessels, trophic disturbances of moderate extent and of even grave consequences, often terminating in gangrene of one or both lower extremities. Other careful observers declare that the same condition is caused by a proliferation of the intima of the smaller vessels, with progressive occlusion. The probability is that both kinds of lesions from amputated legs in presenile gangrene —in which all the vessels, even to the smallest vasa vasorum and vasa nervorum—are enormously thickened as to the *intima*, can occur. Etiology of thromboangiitis—Sex: The affection seems to occur in males only. Typical forms of the disease in females I have never seen, and there is no mention of such in recent literature. Age: The obliterative process probably begins between 20 and 35. Most of my patients, however, were about 35 when first seen. Condition: Most of the patients were poor, and of the type that seek dispensary relief, but several well-marked cases were observed in private practice, in people of means. Habits: Very few were moderate smokers —the greater part used tobacco to excess. This fact has been remarked by most writers on the subject, as the one good clue to the pathogenesis. There is abundant experimental evidence to prove that nicotine produces aortic degeneration in animals, still, conclusive evidence that tobacco causes arterial thickening and thrombosis is wanting. None of my patients took much alcohol. Nationality: Nearly all of my cases were Russian or Hungarian Hebrews, from no particular climatic zone. Buerger, Walter Stern and Bloomfield report the same. The latter describes one case in an Irishman. (MED. REC., Nov. 8, 1913.) Careful questioning did not furnish any light on the possibility of chronic ergot poisoning from poorly prepared bread in the "old country." Mental state: The patients were all neurotic, perhaps from their suffering; perhaps from heredity. Syphilitic taint: None of my patients admitted syphilitic infection. Before the days of the Wassermann reaction, men of large experience with endangitis declared that this was not a syphilitic manifestation. Buerger and Kaliski report forty cases with negative Wassermann reactions. Mercury and salvarsan have proven of no benefit in the men I have observed.

The earliest symptom is pain, grinding, tearing, aching in the back of the calf, the tarsus, ball of the foot and toes. The dorsalis hallucis, the dorsalis pedis, and the posterior tibial vessels are most liable to obliteration. The dorsalis hallucis gives off a metatarsal branch that descends to the sole, joins the plantar artery, to form the plantar arch. This anastomosis is formed at quite an angle: is thus subjected to an unusual amount of trauma, and has been the site of a thrombosis in two cases that puzzled colleagues of much wider experience than mine. The early symptoms give more trouble as time goes on, pain becomes more severe, all sorts of paresthesia, tingling, burning, are more or less constant. There is swelling, puffiness of the toes and dorsum of the foot, and at first, relief from elevating the foot. Patients complain that they cannot walk further than three or four blocks without pausing for several minutes for rest from the cramping, grinding pain. As matters progress pain is torturing, constant, ulcerations appear at the bases of the toes, or behind the edges of the toenails, and there is no relief from the elevated position. After a varying length of time, sometimes several years, gangrene of the toes or the large toe may appear. Physical signs: One is apt to be consulted when the foot is in a state of congestion; the dorsum of the foot is of a purplish blue, or a mottled magenta color. This may extend as far up as the knee. The foot may be cold, or the patient may complain of inability to keep it warm. There is not much edema, but the chronic obstruction to the circulation induces some thickening of the subcutaneous tissues. The reddened condition of the limb, called erythromelia by Buerger, disappears

rapidly or slowly by raising the foot well above the level of the hips. The earliest palpatory sign, even before the occlusion of the dorsal vessel of the foot, has been, in some of my cases, a marked tenderness of the posterior vessels, deep in the tissues of the calf. A periarteritis, which is quite characteristic, marks this line with distinctness and can be palpated when the knee is flexed and the foot relaxed. To feel the dorsalis pedis pulse both feet should be examined; look for a short vessel a finger's breadth to the outer side of the tendon of the extensor of the great toe as it passes in front of the ankle.

As the thrombus formation is localized to the smaller vessels at first the popliteal and posterior tibial arteries pulsate until the lesion has become more advanced. However, there have been cases in which the femoral had shrunk in size, and the lower ones were not detectable at the end of the first year of the illness. In about one-third of the cases the complication of venous thrombosis occurs. A short length of some saphenous branch is affected, a favorite site being at the inner side of the leg or foot. There is a red, indurated line of tender, thickened vein, adherent to the skin—cordlike—and not attended with much edema. This thrombophlebitis shows a great tendency to migrate, may be rarely found in the upper extremity, and indicates the wide-spread nature of the process. The following history seems to include a goodly number of the incidents of a well-defined presenile obliterating angitis, interesting because I have watched his progress for ten years: A Russian tailor, now about 53 years old. Smokes 20 cigarettes a day, in spite of the havoc that the habit has caused. He suffered for 18 months when he was 33, from neuralgic pain and coldness in the right hand, with red and blue swelling; this affection was the explanation of a pulseless right radial, at his first visit, when 43 years of age. During this year he suffered for three months from a frank thrombosis, from the base of the first metatarsal to the internal malleolus, on the right foot. Cyanosis of the toes and dorsum of the foot were visible; no dorsalis pedis pulse. Had lost 15 pounds in weight. He was examined by Dr. H. S. Patterson, who found the first sound of the heart of poor quality; general emphysema; abdomen negative; urine negative; all nerve tests negative. Carbolic acid applications were used regularly, and salicylates were administered internally for a time. This right foot troubled him less and less, but two years later he noticed a slight soreness in the *left* foot, which became gangrenous during his 47th year, and was amputated at the Mount Sinai Hospital. One year later he suffered considerably from obstruction of the circulation in the left hand, and at the end of this year a well-marked phlebitis appeared on the ulnar side. The left radial current seemed to course through the superficial volar artery. During the past three years he has been rendered miserable from periodic attacks of spasm or partial obliteration of the branches coming off from the abdominal aorta—a phase of this condition that has been described by G. A. Friedmann.

Treatment: The palliative treatment of well-marked endarteritis obliterans interests orthopedists because surgical treatment has offered so little hope, excepting when amputation was performed. Palliative measures that are of value are, first, posture. Patients are kept in bed for a period of six weeks, with the feet elevated above the level of the hips. In case of fissures or ulcers, dry antiseptics of a bland nature are used as dusting powders. Reports of successful *x*-ray treatment have been received. For the painful feet of ambulatory cases, 10 per cent. guaiacol-glycerin has proven of value. Daily baking of the limb should be tried. Fifty per cent. ichthyol ointment seems to relieve the painful thrombosis. For a number of years, when there has been no evidence of ulceration and where the patients can be kept under control, I have applied carbolic acid. The dorsum of the foot, soles, and both surfaces of the toes, are wiped with pure phenol on a wad of cotton, and, a minute later, carefully flushed with alcohol. The vasoconstrictor fibers in the skin are powerfully stimulated, for the part quickly blanches, and the current is driven into the deeper vessels, whose circulation is stimulated. This is the only explanation that has occurred to me for the noteworthy improvement that followed soon afterward. The applications can be repeated at weekly intervals—many patients asked for it. Encouraging reports are seen from the side-tracking of the arterial stream. I have seen four cases operated upon that seemed to have derived decided benefit. I have seen a larger number of total failures and believe that there is hope for the suitable early case, whose femoral has shrunk but little. Bernheim's work in this connection deserves praise—his operation is a side-to-side anastomosis between the femoral artery and the femoral vein. He allows a portion of the circulation to proceed through the diseased arterial trunk. Without anastomosis, a gangrenous toe can be amputated without the use of hemostatic forceps—the vessels do not gape, the operation is bloodless. After a successful side-tracking, the veins spurt in a fashion as lively as in a normal foot. Out of seven operations for thromboangitis obliterans, Bernheim reports four successes. He warns "against operating when the patient is too debilitated to stand any operative procedure," and advises ruling out "those in which artery and vein are evidently obstructed, or markedly sclerosed." An exploratory operation is suggested, in cases of doubt as to the suitability of the vessels for anastomosis, and amputation is advised at that time if the vessels are found too badly thickened. He insists that the operator be a man of experience and good judgment in vascular surgery. This new field, opened by the masterly work of Carrel, is widening every day, and bids fair to be very fruitful of benefit to the sufferer from vascular disease of the extremities.

Scleroderma is allied to the foregoing because of the almost constant finding of thickened arteries. An advanced case of scleroderma was brought to my office to attempt to mobilize his joints. He was an emaciated individual, with the skin tightly drawn over the bones, and the joints were stiffened by the binding of muscles, fasciæ, and tendons, to a greater degree than an ossified man. The spinal muscles had not escaped, and he could neither stand nor sit, without discomfort. A slight amount of benefit was derived from the painstaking use of Zander machines, stretching, and massage. Several years later he died from a generalized tuberculosis. Another patient complained of stiffness of the finger joints and carpus, as well as the ankles and feet. There was an advanced chronic parenchymatous nephritis, from which the patient, a married woman of 38, died six weeks later. This patient derived some comfort from judicious massage treatment.

591 Lexington Avenue.

## A SIMPLE EFFICIENT EXTERNAL NASAL SPLINT.

By S. E. PENDEXTER, M.D.,

EAST ORANGE, N. J.

ASSISTANT SURGEON, THROAT, NOSE, AND EAR DEPT. OF THE THROAT, NOSE, AND LUNG HOSPITAL, NEW YORK

In reducing fractures of the nasal bones, or in the surgical correction of external nasal deformities it is often desirable to have an external nasal splint.

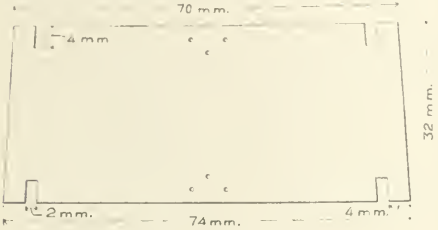

Fig. 1.—Pattern

The functions to be desired in an external nasal splint are, first, protection to the nose, especially during recovery from the anesthetic, and during sleep when the ununited bones are easily displaced; and second, support to the bones of the nose. The writer has been unable to obtain a splint in the market which combines the desired protection, with an adjustable support for the nose.

The following splint was devised, and has been found very satisfactory in the writer's hands. The splint should be made of a malleable metal which

Fig. 2.—Rubber tube slit to fit splint

will be sufficiently rigid to afford ample protection, and yet to be easily moulded to conform to any shaped nose. Thin sheet brass answers the purpose very well and this can be plated to prevent corroding.

The plate may be made as in the above plan. The notches in each of the four corners are to receive the rubber tubes and the perforations for retention stitches. The plate should be rolled in the middle so that the perforations are at either extremity of the rounded bridge, and the two edges forming the base are each parallel with the bridge but

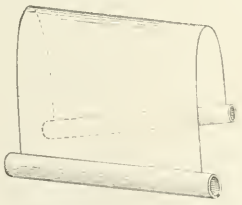

Fig. 3.—Semidiagrammatic view of splint.

form an angle with each other, which may be varied to conform to the angle of the two sides of the patient's nose.

Two thick-walled rubber tubes, each about 6 mm. longer than the sides of the splint, and with a 4 mm. bore may be slit lengthwise, leaving about 8 mm. intact at each end. These tubes can be easily stretched over the sides of the splint and they are held in place by the notches. Thus the tubes form a soft cushion for both edges and for all four corners.

The only point of contact with the nose should be through the rubber tubes along the posterior border of the nasal bones and on the nasal processes of the superior maxillary bones. The pressure should be moderate and directed from before backward. This

Fig. 4.—Splint in position

may be maintained by one stitch through the periosteum of the glabella, and another through the cartilaginous portion of the nose, thereby supporting the nasal bridge.

Adhesive plaster strips extending over the forehead and malar bones in such a way as to cross over the nasal splint are very convenient and serviceable to hold this splint in place. When in place this splint forms a perfect fracture box for the nasal bones, and cotton can be placed within the splint to make gentle pressure where desired, and to serve as a dressing in case a compound fracture exists.

The writer has found a gauze pack to be the best intranasal support to use in conjunction with the external splint.

6 South Arlington Avenue.

## LACERATED CERVIX UTERI AND REFLEX IRRITATION.

By I. WILLIS BALLARD, M.D.,

OPELIKA, ALA.

How many women there are who date the beginning of their ill health from the birth of their children? What a large percentage of gynecology is the direct result of childbirth. Much earnest endeavor is given by physicians to the prevention of those conditions which otherwise would result in deterioration of the mother's health. Proper antepartum attention, painstaking asepsis, the timely assistance of nature's efforts during labor, and proper care of a lacerated perineum after delivery constitute those measures which should always be employed as a means of insuring to the mother a return to normal health.

Despite our best efforts, however, we realize that there are a large number of women who never seem to recover from their confinement. The determination of the reason of such failure is sometimes most difficult and it is the consideration of certain almost universally overlooked causes in this condition that we shall undertake.

As a rule a history of their confinement will not reveal anything out of the ordinary. The first few weeks postpartum they did well enough; then their improvement came to a standstill. They did not regain their usual strength; they would pass entire days in a nervous, irritable state. The physician called to see them realizes they are not improving as they should, and furthermore, that the tonics, change of air and what-not prescribed for them are apparently of but little, if any, benefit. They are not sick enough to be confined to their bed, yet they are by no means well. An increasing weakness, a total incapacity for any prolonged, physical effort is the basis of their complaint. They become more nervous, at times unreasonably cross and irritable, or greatly depressed and morose. Commonly their symptoms show exacerbations at intervals, when in addition they are tormented by a greatly increased frequency of urination, accompanied with most urgent desire and followed by an uneasy, unsatisfied feeling afterwards.

These patients nearly always complain of digestive disturbances. Pain, fullness, and oppression after eating, and in some cases attacks of so-called pseudo-angina, with severe pain in the region of the heart are usually their complaint. Their voluntary limitation of diet at times results in its reduction to such an extent as to be insufficient to maintain nutrition, and the consequent pallor and loss of weight may at first cause one to suspect severe organic disease. They frequently are firmly convinced that they have heart disease or cancer of the stomach. Call these patients neurasthenics, hypochondriacs, or what-not, the fact remains that treatment based upon the statement of the patient and the asking of a few questions will not relieve them. I am firmly convinced that the principal reason why we do not have better results in the treatment of these patients is because we do not examine them carefully enough, or because when examining them we do not appreciate the importance of our findings.

Other than a determination of the presence of a secondary anemia and an abdomen rigid and generally sensitive, our examination will frequently proceed as far as the pelvis before we find appreciable pathology and this is all too often overlooked. I do not refer here to pelvic infections with gross pathology. These should certainly be readily diagnosed. I have reference rather to the less gross pathology of the cervix uteri, which, I repeat, frequently escapes detection during the ordinary vaginal examination.

In all cases included within the class under consideration, careful examination has revealed a pathological condition of the cervix uteri, either as an irritable, exceedingly sensitive laceration or as a hard contracting scar tissue formation. In the latter instance no actual solution of continuity of the cervical tissues may be found upon vaginal examination because during the course of months the laceration has become filled with scar tissue. Yet this incarcerated scar tissue, wedged into the hard unyielding body of the cervix, is, I believe, of far greater importance as a source of reflex irritation than is a cervix, perhaps widely lacerated, but the edges of which laceration have healed without becoming united with the enclosure of a mass of hard contracting tissue.

The determination of the presence of such a partly healed laceration may be difficult and requires a speculum and the careful use of the probe. Frequently there is a dimpling at the lower edge of the cervix at what was the base of the laceration and the smooth outline of the cervix is altered at this point; it gives one the impression of being contracted. Application of the probe to this point will reveal the fact that it is very sensitive and the use of the probe in the cervical canal will demonstrate a linear area of marked tenderness extending upward in the line of the old tear. There is usually but one such area because the cervix usually tears in but one place. I recall a patient in whom pressure with the probe upon this scar tissue would greatly increase the severity of a pain in her back, from which she constantly suffered. Pressure nowhere else about the cervix had any effect upon this pain and it was relieved entirely and immediately upon the operation of excision of this mass of scar tissue.

A second source of marked reflex irritation in this class of patients is the rectum. An irritated, tightly contracted sphincter muscle is an almost invariable finding, the introduction through which of the plain gloved finger becomes most painful, this in the absence of fissure of the anus. Hemorrhoids are so nearly invariably present, small, red, and irritable, that their presence may be assumed without a speculum examination. The treatment of these patients is to a high degree satisfactory and the results of conscientious effort are all that could be desired.

One of the first essentials preliminary to the requisite operative treatment is to relieve the intestinal stasis which frequently has developed coincidentally with the general condition. This is best accomplished by using colon irrigations with large quantities of warm normal salt solution over several days. Second, by means of daily boroglycerin tampons, one should draw off as much of the serous congestion of the cervix as possible. If a retrodisplacement is present one should use a tampon of sterile wool placed in front of the cervix. To support a retroverted uterus the usual tampon placed in the posterior vaginal fornix is practically worthless. By thus holding the uterus forward, the torsion of the broad ligaments and their contained blood vessels is overcome, facilitating the relief of the congested uterine body.

When we have obtained a soft cervix and a clean intestinal canal, we are ready for the necessary operative procedure. Dilate and curette the uterus and if it is large, soft, and freely bleeding, there should be inserted a packing of narrow sterile gauze to be removed after twenty-four to thirty-six hours. Next and most important, the cervix should be amputated. This is usually preferable to attempting to remove all the scar tissue and obtain primary union without the development of more scar tissue. A torn or relaxed perineum should be repaired, and finally the anal sphincter should be thoroughly dilated and all hemorrhoids, crypts, and papillæ removed. Citations of a number of recent cases will prove conclusively that after the above procedure these patients will then be in condition to realize the benefits of proper dietetic and tonic treatment.

# SALVARSAN IN NONSYPHILITIC DISEASES;

## A PRELIMINARY REPORT.

By WM. H. BEST, M.D.,

BROOKLYN, N. Y.

ASSISTANT VISITING PHYSICIAN, DEPARTMENT OF SYPHILIS AND CUTANEOUS DISEASES, KINGS COUNTY HOSPITAL.

AFTER the furor following the introduction of salvarsan abated, and the drug assumed its rightful place in the therapy of syphilis, investigators the world over began the use of this drug in other than syphilitic diseases, for the purpose of enlarging its sphere of usefulness.

Shortly after we started the routine use of salvarsan at Kings County Hospital in the treatment of syphilis, we noted the coincident improvement of the tuberculosis in several cases of syphilis complicated by this disease. Thinking at first that the apparent response might be explained by a mistaken diagnosis (the pulmonary lesions being specific instead of tuberculous), in subsequent cases such measures were taken as to establish conclusively the existence of a tuberculous condition. Lessened cough, lessened expectoration, disappearance of night sweats, increase in weight, improvement of appetite, were noted in different patients. It was this rather unthought-of and unlooked-for result that first stimulated our attention to the possibilities of salvarsan in non-syphilitic diseases.

For the past three years, on the service of Dr. J. M. Winfield at Kings County Hospital, we have taken advantage of such opportunities as presented to treat a number of non-specific conditions with salvarsan. The diseases treated by us include cases of anemia, chancroid, filariasis, epithelioma, leprosy, lupus vulgaris, pityriasis rubra, psoriasis, tuberculosis, and trichinosis.

From our work and the work reported by other investigators it can be seen that some diseases respond as readily to salvarsan as does syphilis, that some act indifferently toward it, and still others are absolutely uninfluenced. The diseases in which the most brilliant results have been obtained are filariasis, frambesia, relapsing fever, Vincent's angina, amebic dysentery, malaria, and chorea. In fact, salvarsan here seems to be as specific as it is in syphilis. It will be noted that the etiological factor in the first four of these diseases is a spirillum of some variety, and it is as a spirillicide that salvarsan has reached its highest efficiency. In Vincent's angina the local application of salvarsan, either in the form of a dusting powder or suspended in glycerine, has given the same good results as the intravenous or intramuscular mode of administration. In scurvy, dermatitis herpetiformis, variola, and ulcus tropicum, salvarsan has shown a very definite influence on the disease, cutting short the course in some and modifying the severity in others.

A number of diseases have been treated in which the results have been very diverse, some cases of the disease showing improvement and even apparent cure, while in other cases of the same disease the results were negative. Some of the diseases showed immediate improvement after the injection only to relapse and pursue their regular course. In this group are included such diseases as anemia, keratosis follicularis, lichen planus, pemphigus, pityriasis rubra, Aleppoboil, leprosy, tuberculosis, and some of the tuberculides. In anemia, keratosis follicularis, lichen planus, pemphigus, and pityriasis rubra, arsenic has always been recommended and extensively used—with no constant results, however; and we find that salvarsan affects them with the same irregularity. In Aleppoboil, leprosy, and tuberculosis, the invading organisms occupy a protected position in the tissues, and hence the results obtained are in proportion to the number of organisms that can be reached by the salvarsan and destroyed.

A host of other diseases, among which are carcinoma, chancroid, erythema multiforme, Hodgkin's disease, psoriasis, rhinoscleroma, sarcoma, scarlet fever, trichinosis, and trypanosomiasis, have been treated with salvarsan, but with uniformly negative results.

It is with those diseases in which indifferent results were obtained that we are most concerned, and it is against these diseases that the efforts of the future should be directed. Our investigations are still being pursued with the idea of discovering the underlying factors that govern the success or failure of salvarsan in the treatment of nonsyphilitic diseases. It is also hoped that by a modification in the mode of administering salvarsan, or by the judicious combination of salvarsan with some other drug or drugs, more uniform and more permanent results may be obtained in those diseases which up to the present time have responded indifferently or sporadically to it.

# Medicolegal Notes.

**Hypothetical Question—Basis of Opinion.**—In an action for personal injuries the plaintiff claimed to have sustained a fracture of the skull, a lesion of the brain which resulted in a partial or complete paralysis, and anesthesia of the right side. One witness testified that the plaintiff had been hit with a piece of plaster about 11 x 16 inches in size, another that it was only about 9 x 4 inches. One witness testified that after the plaintiff was struck by the plaster about a tumberful of blood flowed from his right ear, while another testified that only a small quantity of blood flowed; that it merely trickled out and coagulated. The attending physician testified that on seeing the blood flow from the ear, he diagnosed the plaintiff's injury as a lesion of the brain, while another physician testified that a few weeks after the injuries he concluded from the increasing paralysis that the plaintiff had sustained a fracture of the skull. To prove that the paralysis and anesthesia resulted from the injuries, the plaintiff's counsel called two medical experts, to whom he propounded a hypothetical question, which instead of containing a statement of the facts which the plaintiff claimed to have proved, contained a recital of the conflicting testimony and the opinions of the physicians who had attended the plaintiff. This was held to be error.

A hypothetical question put to an expert witness requires him to give his opinion based entirely upon an assumed state of facts. This question did not ask for an opinion of that kind. The experts, instead of being asked to assume that a tumblerful of blood had flowed from the plaintiff's ear, or that only a small quantity had done so, were permitted to decide for themselves just what the fact was; so, in regard to the size of the piece of plaster which struck the plaintiff, and the diagnoses of the two attending physicians. The result was that when the experts answered the question that in their opinion the injuries received by the plaintiff were the cause of his then condition, the jury was unable to say upon what facts that opinion was based. In other words, the experts might have assumed the existence of one state of facts, the jury have found such facts had not been proved, and yet it would be unable to say that the experts' opinions had been rendered upon facts not proved. The question should have been so formed that the answer when given would have enabled the jury to find whether or not it was predicated upon facts established.—Causa v. Kenney, 156 N. Y. App. Div. 134. 141 N. Y. Supp. 98.

## GUNSHOT WOUNDS UNDER RECENT TYPES OF ARMAMENT.

THE civil as well as the military surgeon should be interested in this subject, since the same types of weapons are used in civil life as in the majority of the armies of the world. Furthermore, in time of war many civil surgeons are called to the aid of the regular staff. The recent books on gunshot injuries by La Garde* and by Makins† are of unusual interest and have been freely quoted in the preparation of this résumé of some of the characteristic features of wounds under the old and new armaments.

In 1892 the War Department made a series of experiments at real or simulated ranges in order to determine the nature of the injuries which would result from the use of the reduced caliber, high-speed, jacketed bullet. La Garde states that the conclusions were: "(1) The shock impressed upon a member increases with the velocity whether a bone is traversed or not. It is always greater with the larger caliber leaden projectile. (2) The explosive effects at very short ranges are about the same for the two projectiles and they continue so up to about 350 yards. (3) The smaller frontage of the jacketed bullets causes them to inflict injuries resembling subcutaneous wounds when the soft parts alone are traversed, and the small wounds of entrance and exit and the narrow track of the missiles are favorable circumstances to rapid healing. (4) The blood vessels are seldom torn by the small jacketed bullet and when wounded they are not closed so easily by coagulation as those severed by leaden projectiles. (5) Injuries inflicted outside the zone of explosive effects upon the shafts of the long bones always show less comminution with the small bullet of hard exterior. The fissures are often subperiosteal and the fragments are larger. (6) Beyond the zone of explosive effects the projectiles of hard exterior almost invariably perforate or gutter the joint ends of bone and the lesions of the articulations are never so grave. (7) The projectiles of hard exterior lodge less frequently in the tissues than the old leaden bullet. (8) The old leaden bullet more often leaves fragments of lead in the foyer of fracture. (9) As the projectiles of smaller caliber are less apt to lodge or to carry foreign substances into the wounds, we will expect to find fewer cases of suffering due to the remote effects of unextracted foreign bodies. (10) The frontage of the jacketed bullet being much less and the fact that it does not lodge as often as the larger leaden bullet will serve to increase the percentage of recoveries in gunshot wounds of the lungs. (11) Owing to diminished frontage the new bullet will cause less disfigurement in wounds of the face. (12) The projectiles of hard exterior are more humane than the old, resections and amputations will not be so often required hereafter, soldiers will be more often restored to the State useful members of the community instead of cripples and pensioners, and in point of economy the new projectile will confer a great advantage." In general, we may say that these conclusions have been verified by actual experience; but space permits the consideration of only a few of the many interesting facts brought out by the recent wars.

According to Fischer, 22 per cent. of all gunshot wounds in war involve fractures of the long bones. While injuries to the shafts of the long bones at the short and very long ranges are similar to those which were observed with larger bullets of relatively low speed, those inflicted at other ranges are far less severe as to the laceration of soft tissues and splintering of bone, there is less fissuring, the fragments are larger and more apt to remain attached to the periosteum. According to La Garde, these differences are especially noticeable from the 500 to the 1,500-yard ranges. At 2,000 yards the small bullet again shows extensive comminution.

Formerly wounds of the larger joints ranked next in severity to those of the body cavities, while now in but one other location is the comparatively beneficent effect of the new armament more clearly shown. That at practically all ranges there is almost uniform clean cut perforation of the epiphyses with little or no fracture has been shown in all recent wars. In former times the bone was fragmented and extensively fissured and these cases were almost always septic. In the Civil War the mortality from wounds of the hip was 84.7 per cent.; of the knee, 53.7; ankle, 26.7; shoulder, 31.1; elbow, 9.4, and wrist, 12.9 per cent.; while in the Spanish-American War the mortality in wounds of the hip was 33 per cent.; of the knee, 5.5 per cent., and there was no mortality for wounds of the other joints. In the Manchurian campaign Follenfant found 1,382 injuries of joints with but 7 deaths and 72 resections. La Garde states that "as far as is known no amputation resulted either in the Spanish-American or Boer wars for gunshot of a large joint by a small jacketed bullet. Primary excision for gunshot of the larger joints is correspondingly rare. * * * We do not recall a formal excision of a joint (at Santiago ) for the mechanical effects of the Mauser bullet. There were 17 cases of gunshot injury to the knee. These were immobilized and shipped North, and 82 per cent. of them were restored to duty in a few months."

*"Gunshot Injuries," by Colonel Louis A. La Garde, U. S. A. Medical Corps (Retired). New York: Wm. Wood & Co., 1914.

†"Surgical Experience in South Africa," by George Henry Makins, C.B., F.R.C.S. New York: The Oxford Press, 1913.

In wounds of the spine, on the other hand, the mortality is higher than formerly. In the Civil War Otis found the average for all regions to be 55.5 per cent., while in the Spanish-American War the mortality was about 75 per cent. This increase is due to the fact that the small jacketed bullet is not stopped very much by the soft parts, passes directly through the vertebræ and shatters the processes, the flying splinters of bone acting as still further instruments of destruction to the cord and membranes. The cord may also be indirectly injured and suffer concussion, contusion, intra- and extramedullary hemorrhage. According to Makins, these injuries may come from "vibratory force communicated to the cord by its enveloping bony canal."

Injuries of the head at proximal ranges are of the explosive type. La Garde says: "Extensive fissures radiate toward each other from the points of entrance and exit. Fractures of the base through the sphenoids and temporal bones are not uncommon and instances are described in which the skull cap and the skin covering it have been literally torn away." In the Civil War the mortality for all types of cranial injuries was 59.2 per cent. The British surgeons in the Boer War "carried out the policy of early, thorough, and careful exploratory work in all head cases" with an average mortality of only 29.1 per cent. In injuries of the face there was much less disfigurement than under the old armament. Wounds of the neck are not nearly so fatal as formerly. Secondary hemorrhage was a very important factor in the death rate in these cases in the Civil War, and this has been almost entirely eliminated. Aneurysm of the great vessels of the neck is, however, much more frequent than formerly, and the same is true of the incidence of aneurysms in other parts of the body, especially the extremities. In the Franco-German War aneurysm occurred once in 2,000 cases, while in the Boer War Graf found 4 per cent. of the wounded had some form of traumatic aneurysm. Arteriovenous aneurysms are being reported in increasing numbers from the recent wars. The injuries to blood-vessels appear to be one of the chief characteristic lesions of the new bullet. It cuts the side of a vessel or scoops out a hole in a large vessel like a cutting instrument, leaving a band on each side of the openings. The cut edges are not lacerated and external or, more frequently, internal hemorrhage takes place at once. In the body cavities this hemorrhage is very fatal.

Under former conditions chest wounds comprised 8 per cent. of all those treated in war hospitals. With present day field tactics the percentage is greater. The comparative beneficence of the new bullet is most strikingly shown by the reduction in mortality in penetrating wounds of the chest. Under the old armament Otis records 8,715 cases with a mortality of 62.5 per cent. In the Crimea the French army had a mortality in these cases of 91.6 and the English 79.2 per cent. "Generally speaking, 60 per cent. of the penetrating gunshot wounds in former wars killed. In campaigns which entailed privations * * * the mortality was rated above 90 per cent. * * * Out of 283 cases reported from the Spanish-American War and Philippine insurrection our mortality was 27.5 per cent." Out of 214 cases treated in the Boer War 30 died, a mortality of 14 per cent. "Oettingen, from the Manchurian campaign, says that when injuries of the lungs were simple they were among the most harmless of those met in war. Follenfant collected the results in 945 gunshot wounds of the lungs and pleura in the hospitals at Mukden with a mortality of 3.67 per cent." The reason for the higher percentage in the American report is that the field stations were near the line of battle and thus many fatal cases were included in the reports which would never have lived to reach the hospitals and be included in hospital statistics. Hemoptysis is present in about 75 per cent. of the cases, lasts 3 or 4 days as a rule, and calls for no treatment. Makins found pneumothorax in less than 3 per cent. of perforating chest wounds by the reduced caliber bullet. Many of the soldiers shot through the lung at Santiago had no dyspnea, pain, or hemoptysis, so that the surgeons found it difficult to enforce proper rest.

It is hard to say just what difference in mortality from abdominal wounds has followed the use of the new armament. Undoubtedly a much larger number are killed outright because of the increased liability to internal hemorrhage and the increased shock from the laceration of intraabdominal organs. When the abdomen has been penetrated visceral perforations are present in 97 per cent. of the cases. The gravity of this class of wounds ranks with that of wounds of the head and spine. According to La Garde, "Penetrating and perforating wounds of the abdomen, regardless of the viscera involved, gave a mortality of 92.5 per cent. in the Crimean War, 90 in the Civil, 69 in the Franco-German, 67.1 in the Spanish-American and Philippine wars, and approximately 56 per cent. for the Russian wounded in Manchuria." The reduced caliber bullet proves deadly at the proximal ranges, especially when the stomach and intestines are filled with solid or fluid material. At mid and more remote ranges these wounds are far less deadly, and there have been many apparently miraculous escapes from death in soldiers wounded in the abdomen at these ranges.

The treatment of these cases should be entirely different in the field from that in civil practice. On the field the best results have followed non-intervention and that is advised except in cases of internal hemorrhage. Under the rule of non-operation, morphine, ice-bag, and no food for days, De Sarlo reported 55 per cent. of cures in the Italo-Turkish War.

It will thus be seen that the principal advantages over the old armament, from the humane point of view, accrue to those receiving wounds in the epiphyseal ends of the long bones or directly through the joints; to those receiving fractures of the long bones at mid ranges; and to those who receive penetrating wounds of the chest without injury to any of the large vessels or nerves; while it is also to be noted that there is less danger of see-

ondary hemorrhage from the laceration of blood vessels, less laceration of soft parts and hence less sepsis. On the other hand, the mortality is increased in wounds of the spine and in wounds of the head at proximal ranges, there is a great increase in the number of aneurysms, and the percentage of deaths on the battlefield to the total number of wounded is greater because of the increased frequency of severe internal hemorrhage and shock from more extensive injury to the thoracic and abdominal viscera. Unless vitally wounded and dying within a few hours, most of those injured under the conditions existing in the recent wars have a much better chance of surviving, and that too without serious permanent functional disability. The future, however, promises a return to inhumanity, for the so-called spitz bullet, which has its center of gravity placed well back and turns sideways upon meeting much resistance, has been adopted by the War Departments of several nations. This bullet, delivered at very high initial velocity, causes even more comminution of bone, epiphyses as well as shafts, and more extensive laceration of soft tissues than the old leaden bullets, for after entering the tissues it turns on itself and passes through the tissues sidewise, tearing and lacerating them fearfully. Hence the mortality and percentage of permanent disability are likely to be increased in future wars when this type of bullet is used.

## THE CARE OF CRIPPLES IN THE UNITED STATES.

To care for cripples properly is now recognized as the bounden duty of every civilized community. Such care is to a great extent an index of the degree of civilization to which a nation has attained and unfortunately also the number of physically deformed is more or less a criterion of civilization. The more a country is engaged in industrial pursuits, the larger is its number of cripples likely to be. Regarded from this standpoint the United States is certainly a very highly civilized country for in the number of its cripples it takes a foremost position. However, with regard to its care of those maimed by disease, by accident, or congenitally, the United States is also in the front rank, and, as in European countries, the right of such persons to be educated so as to be self supporting, if possible, and in any event to have their way made comparatively smooth, is being more and more appreciated. A practical illustration of the concern manifested in the welfare of cripples has been afforded recently by the appearance of the first number of the *American Journal of Care for Cripples*, edited by Douglas C. McMurtie, assisted by an editorial board of medical men, and published by the Federation of Association of Cripples. The publication committee consists of four lady members of the Federation, the president of the Federation being Mrs. George F. Shrady. The opening number is excellent and includes articles by Dr. Gwilym G. Davis of Philadelphia on the "Education of Crippled Children," by Dr. Augustus Thorndike of Boston on "Industrial Training for Crippled Children about Boston," by Katherine W. A. Shrady on the "History of the Federation of Associations for Cripples," by Mr. Douglas C. McMurtie on the "Early History of Care for Cripples," by Dr. H. Winnett Orr of Lincoln, Neb., on "A Statistical Estimate Relative to the Number of Cripples in the United States," and by Grace F. Hardy of Boston on "A Course in Basketry and Cane-seating." The article by Dr. Davis, which was read before the Orthopedic Section of the New York Academy of Medicine, December 4, 1913, describes clearly the character of education suitable to crippled children of different kinds and the wonderful results often obtained. Dr. Davis points out that crippled children constitute a sort of middle class; they should not be driven as totally well children would be driven, nor should they be nursed as sick ones would be nursed. In other words, they should have a distinct, separate, special method of treatment of their own adapted to their peculiar needs. Katherine W. A. Shrady gives an interesting account of the history of the Federation and states that its general object is to coordinate the work of the various societies interested in cripples by the establishment of a central bureau, where a complete registry is kept of all homes, schools, hospitals, aid societies, fresh air agencies, etc., so that cripples may be referred there for information. The statistical estimate by Dr. Orr regarding the number of cripples in the United States places it at 259,754. The article by Grace F. Hardy is an outline of the course of basketry in the Industrial School for Crippled and Deformed Children in Boston. The journal is most commendable in its intention and if it lives up to the high standard of its first number will be from the purely literary point of view of importance. It has a wide field of usefulness, for the lack of such a publication hampers considerably the work of societies endeavoring to improve the lot of the crippled. The journal should and doubtless will be the means of disseminating information among the many rich and charitably disposed persons who are desirous of assisting those who in the battle of life have to contend with physical disabilities brought about by disease or accident.

## MEDICINE AND MATHEMATICS.

The time may be not far distant when it will no longer be said that medicine is not an exact science. Recent developments in medical knowledge have been dependent largely upon the application of mathematical principles to some of its fundamental problems. A lucid thesis on the application of calculus to the medical sciences is presented by I. J. Schwatt in the *American Journal of the Medical Sciences*, March, 1914. He shows how the methods of differential and integral calculus have been instrumental in the discovery of mechanical and chemical laws and processes. But the natural sciences have likewise profited by the application to them of the methods of higher mathematics. It is pointed out that calculus is the very language of nature, all of whose operations proceed by infinite-

ly small degrees. The growth of a living thing is made up of an infinitely large number of infinitely small increments. These are definite quantities that can be handled by the methods of calculus. The laws of optics and acoustics, the principles of electrophysiology, the science and technique of roentgenology, the new methods of sphygmography and electrocardiography, all these make large demands upon mathematical science. René Descartes, the inventor of analytical geometry, is said to have written the first book on physiology published. Borelli, the famous mathematician and physicist of Pisa, wrote a treatise on animal motion. One of the most important of the modern applications of mathematics to physiological research was the work of Wolff of Berlin, who elaborated the "law of the transformation of bone." This law correlates the shape and inner structure of bone with the mechanical stresses acting upon it. "Just as a pathological stress will cause abnormal changes in a bone, so, on the other hand, a deformed bone may be made to return to its normal state by well-directed changes in the stress acting upon it." Upon this law Wolff based his method of treating clubfoot and other bony deformities. Abbot's treatment of lateral curvature is another application of the principle.

Traube's recent work on surface-tension in relation to osmosis, digestion, narcosis, hemolysis, serodiagnosis, etc., is largely based upon physical and mathematical studies. It would appear as if the medical student of to-day must have a good fundamental knowledge of mathematics in order to comprehend many problems and methods in physiology and clinical medicine.

### An American Posture League.

Sir Arbuthnot Lane by his dictums concerning the ill effects on the human system of incorrect posture has recently attracted wide attention to the matter. The manner in which a person lives has much to do with the state of health, and correct physical posture will go some way towards warding off several diseases and disorders. The American Posture League has been formed with the view of educating the people as to proper posture and is concerned with the sitting and standing position of children in schools and of adults in shops, offices, factories, and elsewhere. There is no doubt that education with regard to a healthy mode of sitting and standing, especially of sitting, should be taught and practised in schools. If children were thoroughly trained in this direction at school, not only would physical and constitutional benefits accrue to them at the time, but the lessons learned would never be forgotten. In no country of the world, except it be in Great Britain, could be found a wider field for work of this kind. Whatever may be urged against a universal military service, the fact remains, that it teaches discipline of the mind and body and tends to produce a healthy race. As an example of the truth of this statement, the boy scouts may be pointed to. Since the boy scout movement has gained popularity in America and Great Britain, the physical appearance of the youth of these countries has considerably improved. The American Posture League is working along rational lines and deserves the support of the medical profession.

### Varieties of Nanism.

The number of recognized varieties of nanism has been increased in late years as a result of the study of anomalies of the ductless glands. Woygandt, at a recent session of the Aerztlicher Verein of Hamburg (*Berliner klinische Wochenschrift*, No. 13, 1914), has differentiated numerous types of dwarfs. The first is characterized by normal ossification, good intelligence, and normal genitals and is known as "true dwarfism." Next in order comes the "infantile type," which on the whole is very doubtfully characterized. Third comes the rachitic dwarf, and fourth the well-known chondrodystrophic dwarf. These constitute a special study. Next in order come the already mentioned types of dwarfism due to anomalies of internal secretion, as brought out by various causes—thyreogenic, dyspituitary, etc. These have a marked psychic component and our knowledge of them is in its infancy, aside from myxedema and cretinism.

## News of the Week.

**Tuberculosis Clinics.**—Some interesting figures are contained in the annual report for 1913 of the Association of Tuberculosis Clinics of New York. At the twenty-nine clinics maintained by the Association there were recorded 16,016 new cases during the year, the attendance at the clinics being 34,816. The figures of the Department of Health show a more or less constant total of 30,000 registered cases, while its report for last year gave the number of new cases as 22,671, including 6,000 "not found," which emphasizes the importance of the clinics in the tuberculosis work of the city. The number of children reported as under clinic care increased from 1,780 in 1909 to 8,392 in 1913. In 1909 the visits made by nurses numbered 41,870, while in 1913 they reached a total of 84,305. The number of cases discharged as nontuberculous was 2,679 in 1909 and 7,593 in 1913. The Association believes that the gains in clinic work show a more complete and efficient working of the district system, a greater recognition of the value of preventive work among children, and a more careful and intensive follow-up work in individual families. The educational propaganda being carried on has had definite good results, and the cordial cooperation between the Department of Health and the private clinics has been an important factor in the carrying out of the ideals for which the association has always stood.

**Medal for Gorgas.**—Surgeon-General William C. Gorgas, United States Army, has been awarded by the American Museum of Safety a gold medal in recognition of his achievement in cleaning up the Canal Zone and freeing the country of the fever and pestilences which had previously made engineering work almost impossible.

**Dr. William Hallock Park** has been appointed Dean of the University and Bellevue Hospital Medical College to fill the vacancy caused by the death of Dr. Egbert Le Fevre.

**Bronx Hospital.**—The erection of a hospital for contagious diseases in the Borough of the Bronx seems at last to be assured. Following the protests of neighboring residents as to the use of the tract purchased for the purpose some ten years ago, a committee of the Board of Estimate was appointed early in the year to reconsider the matter, and this committee recommended the purchase of a tract of thirty-three acres in the upper part of the

borough, known as Seton Falls Park, which is very suitably situated for the purpose. The committee's recommendation having been approved by the Board of Estimate, the purchase was finally sanctioned by the Board of Aldermen on April 14. An appropriation of $125,000 of corporate stock which was voted in 1911 for the erection of a hospital on the site then under consideration remains available, and will be used for the construction of the first hospital building at Seton Falls Park.

**Memorial to Dr. Musser.**—In the social service room at the Hospital of the University of Pennsylvania, Philadelphia, there was unveiled on April 15 a bronze tablet erected in memory of Dr. John H. Musser, the founder of the service.

**Smallpox in Hospital and Lodging House.**—Dr. Charles Tidd, an interne at the Philadelphia General Hospital, developed smallpox recently and was removed to the Municipal Hospital for Contagious Diseases. All the employees of the former institution were at once vaccinated, with the exception of those who had only recently been so protected, and as it has long been the practice at the hospital to vaccinate all new patients on admission no apprehension as to the spread of the disease is felt.

The discovery of a case of smallpox in the Municipal Lodging House in New York on April 22 caused a wholesale vaccination of the lodgers and employees—600 in all. The patient was removed to an isolation hospital in Brooklyn, and the house was thoroughly fumigated.

**Fire at Sea View.**—A small fire in the sleeping quarters of the staff of the new Sea View Hospital on Staten Island, N. Y., on April 19, caused considerable commotion and alarm for a time. The members of the staff were forced to leave in their night clothes, but the flames were controlled by the fire brigade of the institution and the damage did not amount to more than $500.

**City Death Rates.**—For the week ending April 18 the death rate for New York City was 14.63 per 1,000, representing a total of 1,566 deaths. This was a decrease of 1 in the total number of deaths as compared with the same week of 1913, when the rate was 15.22. For the first sixteen weeks of this year the death rate was 15.26, as against a rate of 15.42 for the same period of last year.

**Infant Death Rate.**—Figures recently compiled from the statistics of the Department of Health of New York City by the Registrar show a steady decrease in the infant mortality of the city during recent years. During 1913 the number of deaths was 12,442, giving an infant death rate of 37.3 per 1,000, as compared with a death rate of 96.5 per 1,000 in 1891, the year preceding the opening of the Straus milk depots. For the summer months of June, July, and August, 1913, the death rate among children was 38.8 per 1,000, or only 1.5 per 1,000 greater than the rate for the entire year, while in 1891 the summer death rate was 125.1 per 1,000. In 1910 the yearly death rate was 48, in 1911, 43, and in 1912 39.6 per 1,000, and the summer death rate for the same years was 57.4, 46.3, and 41.7, respectively.

**Nurses Graduate.**—At the graduation exercises of the Bellevue Hospital Training School for Nurses on April 20 forty-eight young women received diplomas, and 104 others who had completed a post-graduate course received certificates. Dr. John Winters Brannan, president of the Board of Trustees, addressed the graduates.

**Coffin Seals.**—In order to insure a proper enforcement of Section 141 of the Sanitary Code of New York City, which requires that coffins containing the bodies of persons dying from certain infectious diseases be "properly sealed" or "immediately and permanently sealed," the Department of Health has provided a seal, printed on adhesive paper, to be placed upon the coffin by the undertaker as soon as the body is inclosed therein. The seals will be distributed among the undertakers in the city and the nurses and inspectors of the Bureau of Infectious Diseases have been instructed to make sure that all coffins containing the bodies of persons dying from diphtheria, scarlet fever, measles, and other infectious diseases, are closed with one of these seals. In one or two instances during the past year the Department of Health has obtained evidence that coffins containing such bodies have been opened by the family after being closed by the undertaker, and in one case, under the care of a Christian Scientist, and not reported to the Board of Health until too late to insure a private funeral, the coffin was open throughout the church services.

**Science Healing Bill Vetoed.**—After due consideration, Gov. Glynn of New York on April 23 placed his veto upon the bill passed at the last session of the Legislature, which was intended to legalize the practice of Christian Science healing in the State. The Governor stated that the bill which permitted "any person who ministers to or treats the sick or suffering by mental or spiritual means without the use of any drug or material remedy" to practise in this State without interference, would "open the gates to all kinds of medical pretenders, who would swarm across our borders and pretend to practise medicine upon our citizens." "Under this phrasing of the proposed law," he added, "I am precluded from passing upon the claim of the sincere believers in Christian Science." The Governor also refused to sign Senator Herrick's bill which gave to osteopaths in New York City the right to sign death certificates. The bill exempting drug store employees from certain provisions on the labor law, and fixing a separate schedule of hours for drug store employees was signed by the Governor, who considered the exceptions proposed entirely reasonable.

**Dr. Janeway Called to Johns Hopkins.**—Dr. Theodore C. Janeway has accepted the offer of the professorship of medicine at Johns Hopkins University. Under the new plan adopted at the University this will necessitate the giving of full time to teaching to the exclusion of private practice.

**Cross of the Legion of Honor for Dr. Flexner.**—The President of the French Republic has conferred the Cross of Chevalier of the Legion of Honor on Dr. Simon Flexner of the Rockefeller Institute in recognition of the services rendered by him to science.

**Experimentation to Continue.**—After a conference with the Trustees of the University of Pennsylvania following the close of the trial of Prof. J. E. Sweet for cruelty to animals and the disagreement of the jury, Dean William Pepper of the Department of Medicine announced that the continuation of the experimental work in the medical school was authorized. It was agreed by all that the university owes it to humanity to continue the work without interruption.

**Revision of the Pharmacopœia.**—Under the auspices of the New York Branch of the American Pharmaceutical Association a joint meeting of physicians and pharmacists will be held on the

evening of May 18 at 8 o'clock at the College of Pharmacy Building, 115 West 68th street, New York City. The subject will be "Pharmacopœial Revision." Professor Remington of Philadelphia, chairman of the Committee of Revision, will lead the discussion. It is earnestly hoped that the medical profession will be largely represented.

**Gifts to Charities.**—The Presbyterian Hospital, New York, is one of two residuary legatees named in the will of Mrs. Nellie M. Noe, and it is expected that the hospital's interest will amount to at least $100,000. In addition to this bequest Mrs. Noe left $5,000 to the New York Society for the Relief of the Ruptured and Crippled and $10,000 to the Home for Crippled Children at Rye, N. Y.

The Wesley Hospital, Chicago, has received from Mr. James Deering, the son of its founder, a gift of $1,000,000 as an endowment fund, the income to be expended exclusively for the care of free patients. In accepting the gift the Trustees of the institution voted to change its name to the Wesley Memorial Hospital.

The Hospital of the Holy Family and St. Mary's Hospital, Brooklyn, receive $2,000 each by the will of the late John McNamee of that city.

A number of New York institutions have benefited by the will of the late Mr. Emil Levy of this city; Mount Sinai Hospital receives $2,500; the Montefiore Home, Lebanon Hospital, the Hospital for Deformities and Joint Diseases, and the Jewish National Hospital receive $1,000 each; and the Beth Israel Hospital and the German Hospital Dispensary $500 each.

The Milford Hospital, Milford, Mass., receives a bequest of $100,000, to be used as an endowment fund, by the will of ex-Governor Eben S. Draper of Massachusetts, who died recently.

The New York Skin and Cancer Hospital receives a bequest of $1,000 by the will of Mr. H. B. Thacker of this city, and an equal amount is left to the society for the Relief of Destitute Blind and to the Home for Destitute and Crippled Children.

The sum of $3,000 each is left to the Jersey City Home for Aged Women and Christ Hospital, Jersey City, N. J., by the will of the late Mr. Dudley Fleming of that city.

**Medical Society Elections.**—TENNESSEE STATE MEDICAL ASSOCIATION: Annual meeting at Memphis on April 7 to 9. Officers elected: *President*, Dr. Samuel M. Miller, Knoxville; *Vice-Presidents*, for Middle Tennessee, Dr. Hilliard Wood, Nashville; for East Tennessee, Dr. John Morgan Clack, Rockwood; for West Tennessee, Dr. Samuel T. Parker, Lexington; *Secretary*, Dr. Olin West, Nashville; *Treasurer*, Dr. Charles N. Cowden, Nashville.

HARTFORD COUNTY (CONN.) MEDICAL SOCIETY: Annual meeting at Hartford on April 7. Officers elected: *President*, Dr. William R. Miller, Southington; *Vice-President*, Dr. Frederick T. Simpson, Hartford; *Secretary-Treasurer*, Dr. Albert R. Keith, Hartford.

**The Late Dr. Le Fevre.**—The following minute was adopted at a recent meeting of the Bellevue Alumni Society: "The Society of the Alumni of Bellevue Hospital has learned with the deepest sorrow of the death of Egbert Le Fevre, M.D., Sc.D., LL.D., one of its founders and former presidents, and for twenty-eight years a loyal and active member. The peculiar friendship existing between the members of the society renders his loss an especially personal one. He was held in high esteem because of his wide range of knowledge and unusual ability as a diagnostician and therapeutist. He gave liberally of his time and talents to the uplifting of the profession and to the advancement of medical education and was universally respected because of his inflexible integrity and high professional ideals. The society mourns deeply its loss and extends to his family sincere sympathy in their bereavement."

**Obituary Notes.**—Dr. JULIUS CAESAR LAUER of Long Island City, N. Y., a graduate of the University of Berlin, Germany, in 1893, died in the German Hospital, Brooklyn, from blood poisoning following a bite from a child to whom he was administering diphtheria antitoxin, on April 20, aged 56 years.

Dr. ALLEN F. BARNES of Cambridge, Mass., a graduate of the Harvard Medical School, Boston, in 1902, visiting surgeon to the Cambridge Hospital, bacteriologist to the city health board, and a member of the American Medical Association, the Massachusetts and Middlesex County Medical Societies, the Cambridge Society for Medical Improvement, the Boston Society of Medical Sciences, and the Alumni Association of the Massachusetts General Hospital, died at the hospital, after a short illness from bronchitis, on April 12, aged 38 years.

Dr. CHARLES HUNT PORTER of Springfield, Mass., a graduate of the College of Physicians and Surgeons, New York, in 1908, died at his home on April 16, aged 43 years.

Dr. WILLIAM D. MACQUISTEN of Detroit, Mich., a graduate of the Michigan College of Medicine and Surgery, Detroit, in 1891, died at St. Mary's Hospital, after a short illness, on April 6.

Dr. WILLIAM T. KIRBY of Chicago, Ill., a graduate of the Northwestern University Medical School, Chicago, in 1897, and a member of the American Medical Association and the Illinois State and Chicago Medical Societies, died at the Wesley Hospital, on April 16, aged 40 years.

Dr. SAMUEL C. THOMAS of Milroy, Ind., a graduate of the Eclectic Medical College, Cincinnati, O., in 1858, and a member of the Indiana State Medical Association, and the Rush County Medical Society, died at his home, from paralysis, on April 10, aged 82 years.

Dr. WARREN H. HORTON of Florence, Neb., a graduate of the Kansas City, Mo., Homeopathic Medical College in 1891, died suddenly while in his automobile responding to a call on April 4, aged 70 years.

Dr. DUKE C. DARNELL of Vernon, Texas, a graduate of the Medical Department, University of Louisville, Ky., in 1888, died at his home on April 4, aged 54 years.

Dr. HENRY H. LEE of Wells River, Vt., a graduate of the University of Vermont College of Medicine, Burlington, in 1881, a surgeon in the United States Army during the Spanish-American War, attending surgeon to the Cottage Hospital, Woodsville, and a member of the Vermont Tuberculosis Commission, the American Medical Association, and the Vermont State and Caledonia County Medical Societies, died at his home after a long illness on April 4, aged 56 years.

Dr. ADOLPH A. MARGOLIES of Brooklyn, N. Y., a graduate of the University of Konigsberg, Germany, in 1879, died at the German Hospital on April 20, aged 65 years.

Dr. HERMAN FRITSCH of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1870, died at his home on April 16.

## OUR LONDON LETTER.

(From Our Regular Correspondent.)

CAMPAIGN AGAINST FLIES—PERSONALITY DISTURBANCES IN MENTAL DISORDERS—BIOLOGICAL SIGNIFICANCE OF DELUSIONS—MARRIAGE OF WOMEN IN PUBLIC POSITIONS.

LONDON, April 10, 1914.

We are waging war against flies. The campaign was opened on Monday by an appeal in the press, signed by 123 Medical Officers of Health, for the cooperation of the public in an attempt to get rid of the breeding places of flies and thereby reduce the diseases they spread. Foremost of these, infantile enteritis is terribly fatal to child life and the appeal instances the example of Cairo, where there was a plague of flies in 1909 and 3,000 children under five years old died in two months. The recent visit of Surgeon-General Gorgas, noticed in my letter of the 27th ult., seems to have once more drawn the attention of the public to the success of the war on mosquitos and some are asking the authorities why they do not adopt the same measures to eliminate the nuisance of flies. The appeal of the M. O. H., to which additional signatures are being sent in, may therefore lead to new efforts, but it is the cooperation of the individual householder that is the most important point and it is that which is sought by urging the saving of infant life which could with certainty be obtained. Many deaths, it is shown, could be prevented by reducing the number of houseflies and this can best be accomplished by each householder taking the responsibility of looking after his own premises. In the country farmers are told to dig in the manure at once or if a heap is made to cover it with a layer of earth. In London the serious problem is the dustbin which too many ignorant or careless people do not insist on being what its name implies. Only coal ashes and dry dust ought to be put in it—never refuse of organic matter, whether vegetable or animal. All such should be burned. The futility of attempting to meet the plague by killing the full-fledged insect is shown by an epitome of its life history as follows: The female in spring emerges from her hibernating nook and sets out to lay her eggs, choosing a heap of refuse or filth and lays about 120 eggs at each sitting, of which there are several. In a few hours, if the surroundings are warm, the maggot is born, it eats and grows on the filth around it; in five days it is a chrysalis and in five more is a fly in search of food. Mouth, legs, and body get smeared with its food, so not only does it spread disease by swallowing germs, but furnishes them with a suitable breeding place on its own outside, and, of course, on its wanderings where it can on human food, especially milk, it leaves poison thereon to spread disease. The appeal suggests that this should be taught in the schools and the children told that the fly thus carries about diarrhea, enteritis, fevers, cholera, and other diseases. The boy scouts would be extremely useful by tracking the breeding places and notifying them to the health authorities. The cinematograph might show the life history and the damage caused by interesting films. Many correspondents are contributing to the newspapers suggestions on different points but there is a general consensus of opinion that the M. O. H. appeal to householders hits the mark and that they, if once aroused, will do their part and see that the public health authorities do theirs. The one thing is to overcome the apathy of the public by bringing home to everyone the danger which surrounds their families.

The British Psychological Society met the Section of Psychiatry of the R. S. M. on the 24th ult. to discuss two papers—the first read by Dr. R. G. Rows two months ago on "Disturbance of Personality in Mental Disorders"; the other at the meeting for the discussion, entitled the "Biological Significance of Delusions." Sir George Savage presided at both meetings. At the first Dr. Rows had insisted that the psychogenic and pathogenic etiology were both important—the latter often being, in fact, a sign of some change in the function of an organ outside the brain. His paper was based on the cases of two women whose morbid mentality originated in grave shock from the loss of an intimate friend. The loss of mental balance was shown in strong alternations between sensations. There were also times of apparent detachment of personality, one declaring part of her own self was reposing beside her. The author agreed with those who think that perversion of instinct may be at the bottom of anomalies of mental development. He thought, too, that primary lesions of the sympathetic system might disturb organ sensations and play an important rôle in causing those mental disorders in which change of personality is a prominent symptom.

In Dr. Devine's paper delusions were regarded as the outcome of reactions to experience and day dreams had the same psychological structure. The highest psychic operation was the adaptation of the individual to reality—the coordination between desires and circumstances; but as so high a level of conduct could not always be reached there was a tendency to satisfy desires in inferior mental operations. A tired man went to the theater and was for a time in the realm of romance or childhood. The less he could gratify his impulses the more he fell back on psychoses and in some cases there was antagonism between desires and circumstances. The victim of dementia præcox, whose delusions seemed to be chaotic and meaningless did not succumb to situations of difficulty but defects in his personality hindered him from adjusting himself to ordinary situations. The author related a case in which the defect prevented a patient responding to situations as they presented themselves so that he could not get into real conduct with his surroundings. The resulting delusional formation was an attempt at adjustment, each delusional expression indicating a definite purpose. The patient was keenly sensitive of his incapacity and Dr. Devine regard his phantasy as compensatory—a substitute for efficient action. One result was the patient erected a defensive philosophy for himself which provided food for his internal psychosis.

The president said that in former days one heard much about the "ego" but he was not aware that we knew much more about it. He spoke of changes in feeling which might follow the cutting off of some channel of communication or to visceral and organic disorders.

Dr. Ernest Jones supported the author on the point that delusions were not part of the disease process. He looked on them more as healing influences or like a scar, as evidence of disease—not part of it. He knew that was opposed to the more common view, which estimated the severity of a

case by the delusional intensity Some thought it proper to try to break down delusions by arguments but he thought it unwise for if such a method could succeed it would destroy the biological defence of the patient against the world with which he could not battle.

Professor W. Brown said that in Dr. Rows' paper there was much assumption as to physiological processes explaining psychological disturbances. But if organic sensations might be part of emotion they were not the whole. Sensations might be instances of changes of personality but not part of them. It was not easy to see how toxins could influence changes in personality. Dr. Devine's paper seemed to him more satisfactory—supporting the Freudian view of an early rift in the tests entailing, later on, abnormal changes.

Dr. T. W. Mitchell said Dr. Rows was in touch with the best psychological thought and his paper very useful to those engaged in psychotherapy and so continually meeting cases of disintegration of personality which had not crossed the line into insanity.

Dr. Rows, replying on the discussion, said the two papers were mutually helpful. The cases on which both were founded showed some psychosexual maldevelopment, but what drove these patients across the boundary line he did not know—possibly some toxic influence acting on the brain cells to interfere with nerve processes. He closed with a reminder of the work D. David Orr had done with himself on the effect of toxins on the sympathetic system.

The London County Council discussed on Tuesday the question whether medical women appointed to posts should be debarred marriage. On one side it was said motherhood would interfere with the duties and if these ladies were allowed to marry the same privilege should be given to men doctors in the Council's asylums. On the other side it was urged that thousands of married women rendered public services of value in many capacities. A lady member declared a woman could not, while filling a public office, do her duty by a husband and family which was the most important part of a woman's life. The restriction was not removed.

## OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

### LEGISLATIVE MEDDLING WITH THE HEALTH LAWS—REPORT OF THE COMMITTEE ON INFANT MORTALITY—CONFERENCE OF DISTRICT HEALTH OFFICERS.

MANILA, P. I., February 27, 1914.

THERE is much public interest, particularly in local medical circles, with regard to the large number of bills which have been introduced into the Legislature which have for their object a change in many of the health laws as they exist at the present time. There is a bill to create a Council of Hygiene and abolish the position of Director of Health. The enactment of this measure would make the present Director of Health the subordinate of a number of Filipinos who have had no experience in modern sanitation or health administration. This bill has been passed by the Lower House of the Legislature and is now pending in the Upper House. There is another bill for the transfer of the Philippine General Hospital from the Bureau of Health to the College of Medicine and Surgery. A petition has been prepared by local practitioners objecting to this transfer on the ground that it would give the doctors connected with the Medical School a practical monopoly of government hospital facilities. This bill has also been passed by the Lower House of the Legislature and is now pending before the upper branch. A bill providing for the publishing of the formulas of all the patent medicines in ordinary language upon the label of the bottle and in newspaper advertisements has passed the upper House of the Legislature and is now pending in the Assembly. There are also bills pending for the punishment of persons who publish false advertisements or claims with regard to any medicine, share, stock, etc. There is another bill for more central control of the municipal health service. The Legislature adjourns on the night of February 28 and just what the fate of these various measures is going to be will, of course, not be known until then.

The committee appointed in March, 1912, to investigate the causes of the excessive infant mortality in the Philippine Islands and the measures which should be adopted to decrease it, has finally made its report to the Legislature and has submitted the following recommendations:

"(1) The infant mortality problem, like poverty, ignorance, or any other sociologic problem, is eternal. The study of methods for its relief should be continuous and the application of remedies is a fundamental duty of the State.

"(2) The present excessive infant mortality rate by which 135,000 of the 210,000 potential citizens of the country are sacrificed before they are five years old, and less than one-third of the children conceived live to be one year of age, is a serious menace to progress, a disgrace to our civilization, a criticism of our government, a shame to our Christianity, and a sociologic crime.

"(3) Apologies and excuses will not correct the conditions nor will they much longer be accepted by an advancing civilization. All other countries worth the name are awake and active in the campaign of saving the lives of their citizens with at least the same effort that is devoted to securing police protection, collection of taxes, conservation of forests, or in animal husbandry. This country must apply remedies to this, its most important sociologic and economic problem, or disaster is certain.

"(4) Insufficient funds—lack of money—is the excuse or apology that has been offered for not curing this gruesome canker which is eating at the vital centers of the body politic. The excuse is not valid. A captain who failed to answer a call of distress at sea because he was short of coal would be punished; a police officer who failed in his duty because the odds were against him would be dismissed in disgrace; a fire department that failed short of almost superhuman efforts to save a burning building containing helpless children would be censured and its directors punished; and yet a Christian civilization with a modern form of government will allow more than 100 helpless babies to die a day in the Philippine Islands of easily preventable causes. How long will the excuse of insufficient funds be accepted as a satisfactory explanation of such a state of affairs?

"(5) That *health is a purchasable commodity* is accepted as a fact and bears the stamp of approval of every society organization and student of public welfare work. If the Philippine Islands spent as much for health purposes as it does for police

protection, the lives of at least twenty-five of the infants daily sacrificed could be saved and a vast improvement in the health conditions of others secured. If we spent as much for health purposes as is appropriated for the prosecution of crime and the protection of society from criminals we could save the lives of 10,000 babies a year and improve the health and social conditions of thousands of others who, under present conditions, are destined to join the class of criminals and deficients. An additional one centavo stamp placed upon every letter mailed in the Philippine Islands would furnish money enough to save the lives of 25,000 babies a year and increase the health efficiency and earning capacity of this country enormously. *The cry of 'insufficient funds' is not a valid excuse for a continuation of the criminal waste of human life which constitutes the excessive infant mortality in this or in any other civilized country.*

"(6) More infants die out of every hundred births in the Philippine Islands than die out of every thousand born in Australia. The adoption of the Australian Government methods by this country would decrease our present infant mortality 25 per cent. in two years.

"(7) The authority, responsibilities, organization, personnel, and appropriations of the Public Health Department should be extended so as to provide at least the most elementary sanitary and health protection for 100 per cent. of the population of the country. The department should be an insular organization with greater authority which should be centralized. Provincial and municipal autonomy in health matters is a mistake. The organization of the department should be modified to include divisions of child hygiene, public welfare, public charities, and other important branches of public health and social betterment work which now are being neglected. The personnel should be made up of permanent positions filled by persons selected by a merit system with definite lines of promotion and subject to the orders of the central executive office. The 20 centavo per capita health fund must be increased if the requirements of civilization are to be met in the discharge of generally accepted governmental obligations to its citizens.

"(8) Charity, philanthropic, social betterment, and other public welfare societies and movements should be coordinated and combined as closely as possible with appropriate divisions in the public health service. Government funds for such purposes should be appropriated only to organizations with governmental affiliation.

"(9) Manila and some of the other cities should have a number of combined baby clinics, 'milk stations' or 'gota de leche' units, day nurseries, mothers' consultations, 'welcomes,' etc., where suitable instruction and nourishment may be supplied to the deserving poor. The work of such units should be followed up by visiting nurses.

"(10) In their importance as mortality and morbidity influences upon adults and children, the following diseases and disease conditions take rank in the order mentioned: Beriberi, tuberculosis, diseases of the respiratory system, gastrointestinal diseases, diseases of the nervous system, social diseases.

"(11) The redistribution of wealth and alterations in financial balance are parts of the social, political, and economic evolution through which this country is passing. The question should be studied by competent students and an effort made to counteract the ever-increasing phases of poverty which are developing. Most countries and most large corporations are meeting these requirements by some form of industrial and health insurance. The subject should be very carefully studied with a view to establishing appropriate methods of relief in this country.

"(12) The earnings of unskilled labor must be increased; the cost of living decreased, or material advancement of this people is impossible. The average monthly earnings of unskilled labor in this country does not exceed 18 pesos ($9). The average number of persons dependent upon the earning unit will average four. The money available per person therefore will not buy sufficient good food to maintain the body in health, to say nothing of the other expenses necessary to life and a reasonable amount of comfort.

"(13) It is necessary to have guards at the doors of hospitals in Manila to prevent the entrance of the homeless, the blind, the hopelessly incurable, the aged and the infirm, and others ill and deficient from many causes. According to the official reports of the Director of Health there are more than 2,000 insane persons in the Philippine Islands who should have institutional treatment. These persons are a charge upon poverty stricken relatives and go on propagating their kind without restriction.

There are towns in the country where 10 per cent. of the inhabitants have active tuberculosis and these diseased persons eat and sleep with healthy persons and infants. They go on propagating their kind without any knowledge even that they are causing the death of their own children and without any municipal effort to control the disease. In the same towns, if rinderpest breaks out among the small herd of carabao, the resources of a bureau are called into service and very properly so.

In many places the spleen index shows from 20 per cent. to 60 per cent. of the children to have malaria, and mosquitos breed unrestrictedly about the streets and around the houses. Dysentery and other gastrointestinal diseases continue to be of wide distribution because the sewage and waste is scattered at convenient places about the villages, and even in larger towns but little effort is made to destroy or bury these poisonous wastes and breeding places for flies. A dozen babies in the city of Manila and a hundred elsewhere will die today and every day this year because the mothers have not enough food to sustain their own lives and those of their children. Seventy-five thousand babies are today nursing poor quality milk from the breasts of undernourished and sick mothers, and another 50,000 are eating dangerous and poisonous mixtures given in the name of food. Many of these babies even in the city of Manila are being fed mixtures so badly contaminated that 10 drops of the food injected into a guinea pig causes the death of the animal from blood poisoning within forty-eight hours.

"(14) Nearly 400 public prostitutes ply their trade in the city of Manila under an unofficial system of governmental supervision. Most of these women are infected with gonorrhea or syphilis. More than 75 per cent. of the hundreds of public dance hall girls around Manila are infected with venereal diseases and these diseases are spreading rapidly through all phases of society.

"(15) Your committee has finished its work.

The rather vigorous style used in discussing certain phases of the subject under investigation has been employed advisedly. The problem is a vital one for this country and it is felt that its solution will be possible only with the cooperation of an enlightened and aroused public opinion. The committee disclaims all intention of criticising unduly existing organizations but rather our aim has been to present the facts in such a manner that the responsibilities of our advancing civilization may be realized and so that the governmental machinery charged with improvement in public health and public welfare movements may receive the organization and support necessary for the proper discharge of its duties."

The report of the committee contains over a thousand pages, a large part of which is devoted to a reorganization of the health service and many other matters not bearing directly on the question of infant mortality. It appears to be the general opinion that if the committee had devoted its attention more to its subject instead of criticising existing organizations and other matters of which it could have only an imperfect knowledge and at best could only be of minor importance in view of the other conclusions, the report would have had very much more weight.

A Conference of the District Health Officers of the Philippine Islands was held at the central office of the Bureau of Health in Manila on February 9 and February 16 and many matters for the improvement of the health service of the Islands received attention. The program was as follows:

*First Day.*—Chairman's address, Victor G. Heiser, M.D. "The Disposal of Human Wastes in the Provinces," Vincente de Jesús, M.D. Discussion opened by José Mascuñana, M.D. "Beriberi," Rafael Villafranca, M.D. "Malaria, Etiology, Symptomatology, and Differential Diagnosis," Andrés Catanjal, M.D. "Malaria, Prophylaxis and Treatment," Florentino Ampil, M.D. Discussion opened by Zach Laughlin, M.D.

*Second Day.*—"Necessity for Bureau of Health Approval of Building and Plumbing Permits in the Provinces—House Sanitation," Arlington Pond, M.D. Discussion opened by José Bantug, M.D. "Typhoid Fever and Its Important Features in Relation to Sanitation," Gabriel Intengan, M.D. Discussion opened by Vincente Rivera Sayo, M.D. "General, Uniform Sanitary Improvements Needed in the Provinces—Recommendations," G. I. Cullen, M.D. Discussion opened by Francisco Lopez y Lubelza, M.D. "Act 2156 from a Practical Standpoint—Advantages and Disadvantages," Jacobo Fajardo, M.D. Discussion opened by Andrés Bautista, M.D.

According to the published program, "The meeting of the District Health Officers is held in order that a better acquaintanceship may be established and in order that the vital, every day, practical subjects may be discussed by those most interested with a view of working out more satisfactory means to the end to be accomplished. It is very much desired that every one present will discuss the various subjects freely as it is by sifting the opinions of all concerned that the most desirable methods may be arrived at. Those having other questions to discuss before the meeting will be afforded ample opportunity to do so; in fact, it is earnestly hoped that many of the annoying questions of every day work may be taken up and a satisfactory solution presented."

# Progress of Medical Science.

## Boston Medical and Surgical Journal.

*April* 16, 1914.

1. Some Problems in Nephritis. H. D. Arnold.
2. The Importance of Diagnosis and Treatment of Primary Syphilis. C. M. Smith.
3. Bone Cyst of the Os Calcis. W. P. Coues.

**1. Some Problems in Nephritis.**—H. D. Arnold states that cases of nephritis do better on a low protein diet which requires less functional activity on the part of the kidneys. The degree to which the protein should be cut down depends on the degree of impairment of the renal functions. A rough estimate can be made on the basis of allowing 90 grams of protein in the lightest cases and about 40 grams in the severe or advanced cases. Intermediate grades should have an amount of protein between these extremes, varying according to the severity of the disease. If the symptoms improve and the blood pressure falls, the functional tests are not essential; otherwise valuable information may be obtained from them, even in the present stage of one's knowledge. With the accumulation of more data, the inferences that may be drawn from these functional tests will be more and more valuable. In cases with edema, and also in the cases in which the blood pressure remains high, although the protein in the food is reduced, the amount of salt should be reduced. As a result of further study one should undoubtedly divide the cases of chronic interstitial nephritis into at least two or three clinical types. A better understanding of these cases and a more careful study of the problems of nephritis will lead to more intelligent treatment and resulting benefit to the patient. A proper regulation of the diet—not forgetting to provide a sufficient amount of nutrition—will enable many of these patients to live in comfort for years longer than formerly.

**2. Importance of Diagnosis and Treatment of Primary Syphilis.**—C. M. Smith notes that by early diagnosis and active treatment one can hope to accomplish the following: (1) Abort the disease in a large number of case. (2) Protect the family and community. (3) Prevent the probability of transmission of syphilis to the offspring, some of whom may become a burden to the state. (4) Lessen the possibility of the so-called neuro-recurrences. (5) Probably safeguard the individual against late nerve syphilis. (6) Thus diminishing the likelihood of their becoming useless members of society, if not state charges.

**3. Bone Cyst of the Os Calcis.**—W. P. Coues reports a case of this condition in a boy of 14 years of age who fell directly on the right foot while doing gymnasium work. This foot bothered him off and on since, with considerable aching at times. The pain was especially noted after walking or running. There were absolutely no symptoms from the left heel, the seat of the bone cyst. Examination showed a well-nourished boy. The right heel was painful to pressure over the epiphysis of the os calcis. There was no abnormal thickening made out. *X*-ray of this foot showed an old separation of the epiphysis of the os calcis. An *x*-ray of the left foot was taken for comparison. This showed a bone cyst of the body of the os calcis. The whole of the central portion of the body of the os calcis was involved, the thinning extended down apparently quite close to the plantar surface of the bone. Immediate intervention was not advised, but observation at short intervals with radiographs for comparison with the first picture, and operation should the slightest symptoms arise, were urged. Some two months after this the patient was heard from. The trouble had given no symptoms up to that time.

**1. Operative and Postoperative Treatment of Appendicitis.**—P. Syms states that surgeons are all agreed that operating in the chronic or interval cases is thoroughly safe; in this class of cases death should not occur except when due to an unavoidable surgical accident. The surgeons are all agreed that operation in the early hours of acute cases is a thoroughly safe procedure. In the hands of a skilled surgeon these cases will show almost no mortality. Surgeons are all agreed that operating in the very late stages is a very safe procedure; by this time the patient's powers of resistance have been fully established and Nature's means of defence have played their part; the processes have resolved themselves into localized peritonitis or localized collections of pus; often the pus has but little virulence, sometimes it is sterile. Surgeons are not all agreed on the method and manner of operating. There are two or three factions; one, which the author says is ever increasing in size, believes in quick, definite procedure—removing the appendix and stopping the leak, thus removing the cause, making provision for drainage, inflicting as little shock and traumatism as possible, and depending on Nature to work out a cure, the cause of the trouble having been removed, every effort being made to avoid disseminating, or rendering general a localized process. The other factions, however, attempt to supplant Nature by art, and they inflict an undue amount of traumatism. They endeavor to cleanse the entire peritoneal cavity by washing, flushing, scrubbing sponging, etc. Surgeons are not agreed as to the best time for operating in acute cases. The author believes in immediate operation. He would like to operate in all acute cases in the first twenty-four hours, but unfortunately one does not see these cases at that time, as a rule. Most of the acute cases come too late. The author does not agree with Oschner and Stanton that all cases of appendicitis are localized first. Many of our cases of fulminating appendicitis had spreading peritonitis from the beginning, which became progressively more and more generalized. The author does agree with Ochsner that one should withhold from these patients drugs, cathartics, and food; but he also believes that one should remove from these patients a gangrenous, perforated, leaking appendix at the earliest possible moment.

**2. Operative Mortality in Appendicitis.**—M. S. Kakels states that the greatest factor for safety to life exists in the early surgical treatment of a diseased appendix. In the preparation of the patient, the ideas and methods have changed. There is less elaborate preparation by scrubbing and use of antiseptics, and the patient is not weakened by previous purging. In operating one endeavors to minimize as much as possible injuries to the viscera by less handling, thereby avoiding destruction of delicate tissues and inhibiting exudates and adhesion of opposing surfaces, which so frequently lead to postoperative paralysis and obstruction. The less handling and injury done at operation the greater are the chances that no adhesions will be formed. All unnecessary wounds of the visceral and parietal peritoneum are avoided, and prolonged exposure of the intestines to cold air is guarded against. If there is simply a serous exudate after the appendix is removed the wound is entirely closed, leaving the peritoneum to take care of the fluid. If there is a purulent exudate, a cigarette drain is inserted down to the stump and so placed that it does not lie between contiguous coils of intestine, but rather along the abdominal wall. Another cigarette drain is inserted into the pelvis, also along the pelvic wall, after as much of the pus as possible has been removed. This method of placing the drain obviates in a great measure stasis or ileus. The drains are left only until a channel is formed through which the septic material may escape. The position of a patient after an operation is also an important factor in a successful outcome. The patient is therefore placed in a position which will most favor drainage of the discharge, that is, the ventral and Fowler position. In every instance the author makes it a rule to remove the appendix unless great technical difficulties are encountered, or the patient's condition is such that further manipulations endanger life. The author has no fear of inviting peritonitis by the free separation of contiguous adhesions in attempting to liberate the appendix, for by its removal absorption of toxic products from the appendix ceases, and the tendency to postoperative complications, such ae subphrenic abscess, pylephlebitis, empyema, and liver abscess is avoided, because the offending member, the source of infection, has been eradicated. In the hands of skillful operators, familiar with acute suppurative conditions within the abdomen, there need be no fear. The author points out that the various factors, in order of their importance, which are most essential in reducing the mortality from appendicitis are: First, certain diagnosis and early operation; second, as little manipulation as possible in the removal of the offending organ, the source of infection; third, Fowler's position; fourth, the Murphy drip.

**3. Association of Systemic Disease with Metastatic Ophthalmia.**—C. O. Ring notes that there are certain systemic conditions which by reason of the transference of disease processes by way of the blood or lymph channels are capable of producing violent and widespread inflammation of the eye tunics. The lodgment of a septic embolus carried through the blood stream to the capillaries of the retina or chorioid, with the induction of minute hemorrhages, an inflammatory reaction, the formation of pus, and necrotic degeneration rapidly extending to the anterior tunics of the eyeball; this constitutes the usually recognized tragic picture which is probably best called metastatic ophthalmia. The systemic condition which induces it frequently marks it as one of the most fatal but fortunately one of the rarest of ocular diseases. To quote Alter, the triad of factors necessary for its production are pyemia, embolus, and stoppage. The condition under discussion manifests itself as a sequel of many systemic diseases, in addition to surgical or postpartum infection, such as septic endocarditis, influenza, nasal sinusitis with pus formation, parotiditis, cystitis, otitis media, synovitis, scarlatina, measles, diphtheria, scorbutus, variola, erysipelas, typhoid fever, pneumonia, anthrax, cerebrospinal meningitis, gonorrhea, so called Weil's disease, mixed infections, and suppurating glands. At times ophthalmia results from more trivial conditions, such as furuncles and the suppuration attendant upon the extraction of a tooth. In children suppuration of the umbilical cord, or vaccination may, according to Alter, give rise to pyemia with metastatic ophthalmia. Unfortunately many reported cases give no account of the associated systemic infection. In rare cases of exanthemata the vision is preserved, and

not infrequently in cerebrospinal meningitis; although, as regards the latter condition, one is apt to have an involvement of the eye as an extension by continuity rather than a true metastasis.

**1. Constrictions of the Duodenum.**—M. L. Harris calls attention to a condition which hitherto has not been described. This condition is a constriction of the duodenum of the second portion, giving rise to quite distinct, if not characteristic symptoms, and due to the remains of a definite embryological structure. Strictures of the duodenum due to cicatricial contraction, inflammatory adhesions, etc., are well recognized conditions, but the condition to which reference is here made is of an entirely different origin. In the first case of constriction of the duodenum of this kind which came under the author's observation the condition was thought to be of inflammatory origin, but more careful study of subsequent cases has shown that the condition is due to the abnormal remains of a perfectly normal embryological structure. The author has operated on six of these cases. In studying these cases one finds not only a great similarity of symptoms, but also a similarity of findings at the operation. In all of them one finds a disturbance of digestion, as evidenced by more or less distress in the epigastric region, coming on some time after eating, usually from two to three hours. The distress as a rule does not amount to a pain, although some of the patients did have at times attacks of quite sharp pain in the right epigastric or hypochondriac region. Sometimes the distress was described as a sensation of pressure in the stomach. The information was usually volunteered that the distress was relieved by the taking of food. Nausea was occasionally mentioned, but vomiting seldom occurred. Tenderness in the epigastric region was present to some degree in all of the cases. Chronicity was a distinct characteristic, the trouble often dating from early life. While the symptoms showed more or less defined intermissions during the early history, they became practically continuous after they were well established. Hyperchlorhydria was always present whenever examined for and in Case V was of a very high degree. No occult blood was found in the stools. The symptoms suggest very strongly duodenal ulcer, yet in none of the cases were any evidences found at the operation of present or past ulcers, either in the stomach or in the duodenum. The sharp attacks of pain in the right hypochondriac region, with slight jaundice in two cases, suggested the possibility of gallstones. Whether or not it will be possible to differentiate constrictions of the duodenum of this variety from ulcers of the duodenum by the clinical history alone remains for a wider experience to determine, but an analysis of these cases seems to show that there is an absence of the marked intermissions with bad relapses which are so common in ulcer cases. This might be expected from the permanency of the condition causing the trouble. The absence of the occult blood in the stools would indicate this condition rather than ulcer. The use of the Röntgen ray with the bismuth meal is a very valuable aid in the diagnosis. The long, large caput, showing a dilated first, and perhaps a part of the second portion of the duodenum, with a fixed point at the right of the constriction, in connection with the symptoms above mentioned, should lead one to at least strongly suspect the condition described. The difficulty in differentiating from gall-bladder trouble is shown by the symptoms which were present in two of the cases. When the constriction is well established, the distinct continuity of the symptoms would be an important factor in the diagnosis.

**12. The Disappearance of Sugar in Diabetics after Certain Pelvic Operations.**—E. H. Eising states that there is no doubt that there has been a deviation from the older and more orthodox views in regard to surgical intervention in cases of urgency in the presence of diabetes. Particularly in prostatic disease it has been shown that operation is well borne and that diabetes, if not too far advanced, is no contraindication. That prostatectomy or hysterectomy in diabetes of long duration is occasionally followed by a subsidence or total disappearance of the sugar output is a new theme for which there is no plausible explanation at hand. The author reports two cases of advanced prostatic disease with pronounced diabetes in which all traces of sugar disappeared from the urine soon after operation. Spontaneous cure in diabetes is known, according to Naunyn, although very rarely, and then only after traumatic or syphilitic diabetes of short duration. The instances cited are all cases of advanced and pronounced diabetes. Whether hyperglycemia was present in any of the cases, or whether it persisted after the disappearance of the sugar in the urine is unknown. Von Noorden refers to the marked improvement or cure of diabetes in cases which develop chronic granular nephritis, and are marked by hypertension and cardiac hypertrophy. So far as is known, neither Manges' cases nor the author's were accompanied by granular nephritis. In one of Manges' cases the disappearance of the sugar was incomplete, in all the others it was complete. In the author's first case it is noteworthy that the operation of cystotomy had no effect on the sugar output, although all symptoms of irritation were removed thereby. The wide anatomical distribution of the organs that are known to cause glycosuria in their pathological conditions—that is, the medulla, the pituitary body, the pancreas, the liver, and the adrenals—might suggest that also in the pelvis there exist organs which by their internal secretion in pathological states, disturb the glycogenetic function.

**2. The Minimal Lethal Dose.**—G. Dreyer and E. W. A. Walker conclude that (1) in warm-blooded animals dosage (D) must be calculated in relation to the body surface according to the expression $D = \frac{d}{W^{0.72}}$ where D is the "surface dose" of the drug, toxin, or antitoxic substance used, d represents the actual quantity administered, and W is the weight of the animal in grams. (2) No method, however, at present exists by which a true comparison of the relative toxicity of different substances (or of different samples of the same substance) can be instituted. The methods hitherto employed depend on the selection of an arbitrarily fixed weight of animal and lethal time, and do not afford a rational basis for the accurate measurement and standardization of drugs, toxins, and antitoxins. (3) The formula here proposed

$$\frac{1}{Do - a} - \frac{1}{Dl - a} = k\,(To - Tl)$$

offers a simple means of making such measurements. In this formula Do and Dl are the concentrations of the drug or "surface doses," corresponding to the times To and Tl in which the death of the animal (or other desired effect) occurs; a is a figure representing the "non-effective dose" of the substance employed, and k is a constant to be determined for the particular substance and species of animal under investigation. (4) The formula states that to every equal increment in time there corresponds a definite decrease in the active dose (D — a). (5) This formula is here shown to afford a satisfactory expression for all the varied and diverse experimental data to which it has been applied. (6) The use of the formula renders it possible not only to carry out the comparison desired but also to make use of animals of every size over a wide range of weight within a species and all observed death times, in the standardization of toxic substances, antitoxins, and the like. (7) By this means a great saving both of time and animal material is introduced since an equal value independent of the actual lethal time and weight of individual animal, can now be attached to all the experimental data. (8) The results obtained will also possess a greater validity and a wider application than it has hitherto been possible to attain by the use of an arbitrary death time and a fixed standard weight of experimental animals.

**3. Improved Methods of Standardizing Bacterial Vaccines in Hemocytometer Chambers.**—E. E. Glynn and A. A. Rees reach the following conclusions: (1) The most scientific method of enumerating the bacteria for vaccines is in some form of hemocytometer chamber. (2) An optically plane and rigid coverslip must be used with such apparatus, for this is recognized as essential when counting blood, and is still more essential when counting bacteria, where accuracy is of greater importance. Owing to the small free working distance of oil-immersion lenses most optically plane coverslips are too thick. (3) Two types of hemocytometer chamber may be employed: (a) The ordinary chamber 0.1 mm. deep, with an optically plane coverslip 0.13 mm. thick. This is suitable for all oil-immersion lenses with a free working distance of 0.17 mm. and some of 0.15 mm. (b) A chamber 0.02 mm. deep, with a special safety trench 2.5 mm. wide and optically plane coverslip 0.18 mm. thick. This is suitable for all achromatic oil-immersion lenses, even if the free working distance is as low as 0.09. (4) The 0.02 mm. chamber is much superior for the following reasons: (a) Almost all the bacteria settle at the bottom in 15 minutes when accurate counts can be made, whereas in the 0.1 mm. chamber, a considerable number are still moving after half an hour. (b) Bacteria adhering to the under surface of the coverslip or still floating in the chamber are more easily enumerated. (c) The optical definition of the bacteria is better owing to the smaller quantity of fluid. (d) The free working distance is greater and the coverslip being 0.18 mm. thick is more durable. (e) Counting is quicker owing to the much smaller number of moving bacteria and the greater ease in focusing the top and bottom of the chamber. (5) A weak solution of carbol thionin is the best diluting and staining fluid; unlike a weak solution of Giemsa it is quite free from precipitate and stains more intensely. (6) Enumeration of stained bacteria in a hemocytometer chamber, particularly in one of 0.02 mm. deep, is more accurate and much more rapid than by Wright's method. (7) The hemocytometer method does not underestimate the strength of bacterial emulsion as usually happens with Wright's method, sometimes to a very serious extent. (8) This research has been undertaken because we believe it is the duty of the bacteriologist to standardize and dispense his vaccines with the same accuracy and care as that exercised by the pharmacist in standardizing and dispensing his drugs. Scientific vaccine therapy will be advanced by scientific exactness.

**5. Diabetic Retinitis.**—S. West notes that there is much difference of opinion on the subject of diabetic retinitis. Some maintain that there is no such a thing, others that the retinitis which occurs is albuminuric and due to the association of diabetes with granular kidney, while others hold that there is a form which is perfectly characteristic and pathognomonic. The author has seen many cases of retinitis in diabetes and states that he has failed to observe anything characteristic in it, that is to say, anything by which from the change of the retina diabetes can be diagnosed as granular kidney can. He has had cases shown him more than once which were said to be typical, but they did not convince him, and so far as his own experience goes, he says that it was impossible to diagnose diabetes from anything that can be seen in the retina. He also agrees with the statement that many cases of so-called diabetic retinitis are typically albuminuric, and are due to the association of diabetes with granular kidney, an association which is by no means rare. But this does not exhaust the subject. There are two forms of albuminuric retinitis, which the author has called the degenerative and the exudative, respectively. The exudative form is in all cases of toxic origin, and might therefore arise in the course of diabetes, just as it does in the course of acute nephritis, and this is the fact, for the author has certainly seen cases of this kind in which there was no evidence of granular kidney. The view he is expressing would reconcile and explain the different opinions held. The degenerative form would be characteristic of granular kidney, whether associated with diabetes or not. The exudative form would be of toxic origin and indistinguishable from that which is seen in other toxic states and be due to some poison produced in diabetes which attacks the optic nerve and retina just as it sometimes does the peripheral nerves. What the poison is one knows no more in diabetes than one does in nephritis.

**6. Therapeutic Value of the Potato.**—H. C. Howard states that there are two facts which stand out most prominently and which emphasize in a marked degree the peculiar properties of the raw potato juice. The first is the prompt relief from pain, acute or subacute, which is shown to have occurred and the second the rapid absorption of the fluid in cases of synovitis. It seems on investigation of the juice of the potato that there is no alkaloid in it and that the chief ingredient is potassium salts which are present in large quantity. The basis of all the preparations is the liquid extract. It is made as follows: The raw potatoes are put into a hydraulic press and the liquid is squeezed out. About half the weight of the potato comes away as juice. The starch and nitrogenous matter are removed, leaving the juice with the salts only in it. It is then concentrated down by heat and by glycerine added in order to preserve it, until it is made five times the strength of the juice, therefore ten times the strength of the potato itself. The ointment is made the same strength as the extract, and is prepared chiefly with lard. A liniment is made by taking equal parts of the extract and compound soap or two of extract and one of soap liniment. The plaster is made as ordinary plaster and is of the strength 10 to 1. Ampullæ are prepared containing the pure extract, which is five times the strength of the juice and properly sterilized. The author has yet not had much experience with the hypodermic use of the remedy. The action of the liquid extract on acute synovitis of the knee joint, whether traumatic or gouty, is speedily to relieve the pain, which does not occur, and to cause absorption of the fluid, in four, five, or six days. It is applied as a fomentation or poultice, one part of extract to three or four parts of water on three or four layers of lint, covered with protective, then cotton wool and a bandage, to be renewed every two, three, or four hours, according to the severity of the case, until the fluid is absorbed. No splint is required, but the patient must be kept in bed with the knee in a comfortable position. In gout the local treatment relieves the pain more quickly than any other treatment at present used, either external or internal. One part of the extract to three or four parts of hot water is applied as for synovitis every three or four hours until the pain is relieved. In complaints such as lumbago, subacute rheumatism, muscular rheumatism or fibrositis, and bruises, considerable relief is given by the application of the abstract as shown below. In the various forms of subacute, chronic, muscular rheumatism or fibrositis a liniment made of two parts of ext. solani to 1 part of lin. saponis rubbed on the part will in most cases give relief after the first or second application.

## Deutsche medizinische Wochenschrift.

*March 26, 1914.*

**Rare Disturbance of Potency.**—Flatau relates the following: A man aged 24 had repeatedly had intercourse, but never an emission. The erections and immissio penis were physiological as were the coitus movements. There was no real pleasure, increasing to an acme, but the libido was normal. Occasional masturbation before his first coitus, had caused emissions, and he had also experienced ordinary nocturnal pollutions. He was a robust, healthy man with normal genitals; blushed readily, was irritable and impressionable, and his patella reflex was heightened. There was no aspermatism. The author cites a case reported last year by Lissmann which much resembles his own. Such cases may be classed as examples of "ejaculatory impotence." The nature of the affection is quite obscure and no successful treatment is at present available.

**Pernicious Anemia and Pregnancy.**—Wolff discusses this association thoroughly. The diagnosis of essential anemia is made by the Naegeli-Ehrlich blood count, which indicates abortive attempts to restore the diseased blood picture to the normal count. But in the author's case—in a pregnant woman—a remission of the disease seems documented, which would take it out of the domain of pernicious anemia. In regard to prognosis, the so-called Biermer's anemia almost never undergoes recovery, although remissions of all degrees occur. The etiology of the anemia in the author's case was also obscure, and must naturally be placed temporarily under the toxemia of pregnancy. If the latter term is too vague, we can only advance the view that pregnancy brings out some deep-seated metabolic irregularity. Of crucial importance here is the question "should gestation be terminated?" For even should the condition have become apparently normal, the percentage of recurrences is very high, and the disease may reappear after delivery. The question of interruption of gestation in the earlier months may be left out of question. While in theory the constant drain of the fetus upon the mother should demand instant termination of gestation, the fact remains that in the great majority of cases the anemia does not appear until late in pregnancy, so the rights of the unborn child must be taken into account. Figures show that early induction of labor give poor results both for mother and child, although we have no precise figures as to the ultimate fate of the latter. In cases left to spontaneous delivery the results appear more favorable. A remission may occur during the dreaded post partum period. In case of urgency we may use transfusion. The author allowed his case to go to term and after delivery a remission of the anemia was at once apparent. No other remedial measures were employed.

**Professional Accidents from Radioactive Substances.**—Gudzent and Halberstaedter refer chiefly to dermatological injuries and changes in the blood-count resulting from the use of radium and other radioactive substances. Under the head of general phenomena are considered in addition to the blood count changes in the genital glands. Nearly all those who cooperate in radium institutes suffer at the outset from weariness and insomnia. A large personal equation is involved herein. Women are more sensitive to the radiation and in two, menstrual disturbances resulted. The blood count shows a definite resemblance to that resulting from the *x*-ray. The same may be shown to be true of cutaneous lesions due to radium, which represent in a very small and apparently harmless way seven results of *x*-ray (burns, etc.). For the prevention of radium injuries a technique is in use which is based upon that required to protect the organism from *x*-rays.

**Drug Anaphylaxis.**—T. Silvestri states that drug idiosyncrasy as well as alimentary anaphylaxis may be local or general, congenital or acquired. It may be diminished or increased by the most varied physiological conditions, such as pregnancy, menstruation, etc., or by pathological conditions. It may disappear spontaneously or it may be affected by the administration of certain internal secretions. In a case reported by the author the idiosyncrasy to morphine was removed by the administration of small enemata of laudanum, by small doses of the latter administered by the mouth, by the use of heroine or dionine administered by the mouth or hypodermically, or by the use of minute doses of morphine.—*Il Policlinico.*

## Insurance Medicine.

**Group Insurance—Its Aim and Its Field.**—Judge William A. Day, president of the Equitable Life Insurance Society, in his address before the Association of Life Insurance Presidents, December, 1913, describes group insurance as a phase of the economic and social tendencies of the day for just relations between employer and employed. It has the double function of protecting families of the employed and rewarding efficient and persistent service.

While the interests of our countrymen are interwoven, and we are dependent upon one another, the effects of business derangements are mainly borne by those of limited means. The demands of living in these days leave most American families a margin between living conditions and poverty that is not over-strong. The extensive workingmen's insurance systems of England and Germany were devised largely to ward off the suffering and losses ordinarily caused by temporary unemployment. That something should be done in a comprehensive way in this country to protect against the permanent stoppage of family income has long been patent to thoughtful observers. Individual insurance does its part well, but does not adequately answer the call. Group insurance, like a great wall stretching around thousands of homes provides against distressful poverty. Its widespread adoption would materially reduce the number of women and children annually forced into the struggle with adversity.

Groups must be of sufficient size to present reasonable opportunity for the law of average to operate. Thus far experience has clearly shown that the strong lives support the weaker ones in an average that gives a lower mortality than that secured on individual insurances through regular medical examinations. Of the thousand persons applying ing for employment in response to the advertising, the ultimate sifting would put only a comparatively small number on the permanent payroll. The less intelligent, the less fit physically, and, therefore, the weaker lives, would be eliminated and those who demonstrated aptitude for the work and were employed would have to maintain the necessary level of bodily and mental fitness to continue employment.

From the employer's standpoint, group insurance is the one way by which he can make sure that every man and woman in his employ is covered by insurance. Employers rightly regard it as an effective welfare measure and an opportunity to prove in good faith their interest in those who collectively assure the success of their enterprises.

So far as employees are concerned, group insurance makes life insurance general, at least during the period of employment, and it comes to them without cost in nearly all cases. Group insurance insures the continuance of the pay envelope for a generous period and goes to the heart of the problem by protecting producing values. Usually the amount of insurance is one year's wage and the employer generally supplies this much gratis, leaving to the employee the burden of carrying individual insurance. Group insurance overcomes the procrastination and failure with respect to insurance of which so many are guilty and which leaves so many families unprovided for in event of death. It is a logical and reasonable response to a real public need; it is not in advance of the times.

**Paralysis Agitans Following Trauma.**—The conclusions of Decker on this subject are as follows: Paralysis agitans seldom appears after injury. To decide that there is any connection between the latter and the appearance of the former is in many cases extremely difficult. Only in a minimum number of such cases was the certainty demanded by science established. More frequently there was a sufficient probability or possibility of such a sequence. In all such decisions as to cause and effect, the question of predisposition plays a major rôle, whether this be inherited or acquired. Mendel says of shaking palsy that it cannot be due purely to injury if the subject up to that period had been fully sound including freedom from any neuropathic taint. There is in other words no such an entity as a purely traumatic paralysis agitans.—*Zeitschrift für Versicherungsmedizin*, December, 1913.

**Sensitiveness of Abdominal Organs to Percussion, and Its Utilization in Insurance Practice.**—Goliner mentions the fact that the thorax is percussed far more than the abdomen, although abdominal percussion is much more simple, for here there are no ribs interposed. In using a percussing hammer, the percussion waves set up occasion no painful sensations in the subjacent viscera provided the latter are sound. However, should there be some lesion in the viscera or mucous canals these percutory commotions may cause unpleasant, and even very painful sensations. The skin must be eliminated as a source of tenderness by percussing the tissues beneath. If one organ percussed be superposed above another, the percussion notes concern only the more superficial organ.

While abdominal percussion is simple *per se*, the large number of viscera involved contrasts unfavorably with the small number of intrathoracic organs. Hence with patient upon his back, the viscera not directly involved are pushed away, so that, for example, the inferior border of the liver is made more accessible. One may thus map out the liver and even the gall-bladder. A principal task in this work is to push the hollow tympanitic structures away from the solid organs, so that the latter can be mapped out. There are a number of artifices for bringing this result about. It must not, of course, be overlooked that the intestine itself may be diseased while the viscera are sound. Distended intestines further mask the conditions beneath.

In insurance practice especial attention must be given to percutory sensibility about the gall-bladder and passages—in which gallstones may be harbored—and cancer and ulcer of the stomach and duodenum. In connection with the bile passages, cholangitis rather than the mere incidence of stone, is significant. Given a history of biliary colic, with no interval symptoms, the entire hepatic region should be percussed and if sensitiveness be present the subject cannot be accepted. If the percussion gives a negative result, Goldflam's succussion method may be applied throughout the liver, when induced pain may point to cancer.

The diagnosis of ulcer or cancer of the pylorus or duodenum may be made by an elaborate percutory technique which cannot be detailed here. It is hardly to be supposed, however, that the average medical examiner can profit very greatly from such refinements of diagnosis.—*Blätter für Vertrauensärzte der Lebensversicherung*, 1914, Vol. V, January-February.

# Society Reports.

## MEDICAL SOCIETY OF THE STATE OF NEW YORK.

*One Hundred and Eighth Annual Meeting, Held in New York City, April 27, 28, and 29, 1914.*

(Special Report to the MEDICAL RECORD.)

HOUSE OF DELEGATES

*Monday, April 26—First Day.*

THE PRESIDENT, DR. WILLIAM FRANCIS CAMPBELL, IN THE CHAIR.

**Report of the President.**—Dr. WILLIAM FRANCIS CAMPBELL of Brooklyn stated that it had been his privilege in order better to equip himself for his task to make official visits to the county societies in order to gain a personal impression of the local conditions, the aspirations, and the needs of the individual units which collectively formed the Medical Society of the State of New York. While every county society had not been visited, territorially the State had been fairly covered. It was thus that he hoped to interpret the local needs and aspirations of their profession throughout the State; to suggest such changes as progress demanded, and to promulgate those broad and comprehensive principles of fraternity in which sectional differences were submerged in the greater good of the larger number. It was gratifying to note the activity and increase in membership in the county societies. With few exceptions the membership committees had done effective work, and some of the counties reported that they had secured all the desirable physicians in their sections. There was throughout the State a fine scientific spirit actuating the rank and file of our profession. No longer did the large cities monopolize men of capacity and scientific attainments; the smaller towns were well equipped with hospitals and laboratories, and their efficiency was guaranteed by men of broad culture and recognized ability. The grave danger to an organization like this society, which lacked the cohesion that accrued from frequent meetings and the sustained interest of the majority, was the tendency of its government to drift into the hands of a few; its policies to travel in well-worn grooves, and precedent to take the place of progress. The function of the State Medical Society was not general—it was specific; it was to do for the individual members what they could not do for themselves; its aim was to safeguard the interests of its individual members better and thereby to sustain the dignity of the medical profession in the various communities throughout the State. The State Society served the profession chiefly in four directions—malpractice defense, the *State Journal*, the Directory, and the work of the committee on legislation. After reviewing the work being done in each of these directions the president presented the following questions which seemed to him worthy of consideration:

Can our *State Journal of Medicine* be made self-supporting under different management? Would the entire time of a business manager be more efficient than the sporadic efforts of a committee of professional men? In short, are the *Journal's* possibilities being fully realized, and its business conducted according to modern methods of efficiency?

Can our malpractice defense be made still further effective by the establishment of a legal bureau with a central office, counsel, and assistants, who shall not only conduct malpractice defense, but assist in the prosecution of illegal practitioners throughout the State?

Is the Directory of sufficient importance to the Society, as a whole, to warrant the present appropriation? Would the best interests of the Society be better conserved by publishing the Directory biennially, or by limiting it to New York State, or by contracting with the American Medical Association to bind, in a single volume, that part of their directory which refers to New York State, as is done by other States?

The house resolved itself into a committee of the whole for the consideration of these recommendations, and after a lengthy and sometimes heated discussion motions were adopted to the effect that the *Journal* be continued under its present system of management, since experience had taught them that under a business manager, not a professional man, they were liable to have considerable difficulty in excluding undesirable and unethical advertisements. That the malpractice defense be continued without any change, as the establishment of a bureau such as suggested would involve an outlay of money entirely beyond their means. That the Directory was of sufficient value to the Society as a whole to warrant its publication as at present.

**Report of the Secretary.**—Dr. WISNER R. TOWNSEND submitted this report in which he stated that the membership on January 1, 1913, was 6,964 and on January 1, 1914, 7,239, an increase of 273 members, which was larger than that for any of the last four years. The percentage of paid-up membership was larger than it had ever been. It was with great pleasure that the announcement was made that during the past year the few missing volumes of the transactions of the State Society had been secured and to-day the set was complete from the beginning to the present time. The pleasant task of collecting the portraits of the ex-presidents had also been completed in so far as was possible. There were hanging to-day on the walls of the Society's rooms pictures of 80 ex-presidents. During last summer the Essex County Society had been reorganized and during the latter part of the year the Bronx County Medical Society, which would bring into the State organization many members. There were in the State 62 counties and all had medical societies except two, and these were so sparsely settled as to make it inadvisable to endeavor to form societies. A request had been received from the council on health and public instruction of the American Medical Association asking the State Society to appoint a committee on health and public instruction or modify existing committees so as to provide for an appropriate committee of the Society through which the work of the council might be carried on in each State. It was the desire of the council to carry on this work in each State as far as possible through the officers and committees of the State organization. The committee on Red Cross of the American Medical Association also desired the appointment of members throughout the State to represent it in any case of emergency in which the Red Cross might act. The Workmen's Compensation Commission would be appointed early in the year, before the meeting of the State organization, and it seemed desirable for the Society to appoint a committee of conference of not less than five members, representing different parts of the State, to appear before this commission from time to time to present the views of the profession upon the various questions that would come up for solution. This report was accepted and the recommendations contained therein were adopted.

**Report of the Council.**—Dr. JOSHUA M. VAN COTT of Brooklyn submitted this report in which it was stated that the council had held three meetings during the year, at the last of which the following resolutions were adopted and would be presented to the House of Delegates for action:

*First.* Members shall not be entitled to malpractice defense if the acts in the suit for which they make application for defense were committed prior to their admission to membership in the State society.

*Second.* Members who have been dropped for nonpayment of dues, if reinstated, shall not be entitled to malpractice defense for acts committed during the time they were not members of the society.

*Third.* Active members of the society desiring to avail themselves of the privileges of this act shall make application therefor in writing to the secretary of the Society, and it shall be shown to his satisfaction that they are members in good standing in the State Society. They shall also furnish the secretary a complete and accurate statement of their connection with, and treatment of, persons upon which complaints against them are based, giving dates of attendance, names and residences of nurses and of other persons cognizant of facts and circumstances necessary to a clear and definite understanding of all matters in question, and shall furnish such other relevant information and execute such papers as may be required of them by the secretary or the attorney of the State Society.

*Fourth.* A member shall agree not to compromise any claim against him, nor to make settlement in any manner without the advice or consent of the Society given through its attorney.

*Fifth.* In the event that a member sued or threatened with suit shall, without the advice or consent of the attorney of the Society, determine to settle or compromise any claim against him, he shall reimburse the Society for the expenses incurred in undertaking his defense, and in default thereof he shall be deprived of further privileges under this resolution.

*Sixth.* The Society shall not assume any responsibility for the payment of any sum agreed upon by arbitration in the settlement of claims, or awarded by court verdicts, or for making payments for any purpose whatsoever.

This report was accepted and the recommendations adopted.

The Council further reported that in their endeavor to induce the Regents to raise the preliminary requirements for the study of medicine that they had found that the Regents had no power to act in this matter, the law compelling them to carry out its provisions, which they had found to be faulty. In view of the important matters now pending, such as the antivisection question, osteopathy, etc., it was deemed unwise for the present to urge the Regents to attempt to change the law.

**Report of Committee on Publication.**—This committee reported that owing to the increase in membership the edition was now 8,300 copies per month and that in 1914 it would be 8,500. The cost of publishing the *Journal* was $4,449 for the year 1913, a saving of $1,410 over the preceding year. The cost of publishing the "Directory" was $5,762 in 1912, and $6,043 in 1913. In the opinion of the committee a publication based on the plan of the "American Medical Directory" would greatly lessen the value of the book.

**Report of the Treasurer.**—Dr. ALEXANDER LAMBERT presented this report which showed an excess of income for the past eight years of $5,845.95 and that the cash surplus of the Society had risen from $5,328 in 1906 to $9,448 on December 31, 1913. The report pointed out that they could not hope to increase the sales or the advertisements of the "Directory" or the *Journal* and that any increased revenue to the Society must come from increased membership.

**Report of the Committee on Legislation.**—Dr. LEWIS K. NEFF submitted this report, which was read by the secretary. He stated that during the year the work of the committee had been greatly increased by the large number of bills introduced. The Health bill which was passed was amended in important particulars as the result of the work of the State Society. The attention of the profession was called to the fact that if the Society was to be of any great influence in the future the individual members must do more work. With the proper support from the entire profession any measure they opposed stood a poor chance of passing. If, in the future, measures such as the Osteopathic, Naturopathic, and Chiropractic bills were not to be passed, the profession must realize that every man had his work; otherwise they would see much undesirable legislation placed on the statute books.

**Report of Committee on Public Health.**—This committee, after urging that the State and County Societies do all in their power to further the good measures affecting public health and oppose the bad, and after congratulating the State on the appointment of Dr. Hermann Biggs as Health Commissioner, suggested that a bill be submitted to the Legislature providing for an appropriation of $100,000 for the purchase of radium for the New York State Cancer Hospital for the treatment of epithelioma. The report expressed the belief that the time was at hand for the establishment of filtering plants in cities situated as Buffalo and Niagara Falls where the lake and river waters were so polluted as to make a clean water supply next to impossible. The often reiterated recommendation was emphasized that the State Society should take an interest in definite action looking to the establishment of pathological and bacteriological laboratories in all counties where there existed a demand for them. It was recommended that a committee be appointed to confer with the State Department of Health on this matter. Finally, this report urged that the Legislature be appealed to by the State Society to appropriate a sufficient sum of money to make the quarantine station adequate to the needs of the largest port of entry in the world. The State Society should endorse a request for $2,000,000 for this purpose. Hoffman and Swinburne Islands should be shored up, a modern unit system of pavilions should be built on Swinburne Island and the old buildings on Hoffman Island should be either reconstructed or replaced by modern structures. There should be a central light, heat, power and water plant which would make a great saving of running expenses. And the channel to the two islands should be deepened. We could then point with pride to a Quarantine Station which would be on a par with those of the other great powers. This report was accepted and referred to the Committee on Legislation with power to act. The recommendations contained therein were adopted with the exception of the one relating to the purchase of radium. It was pointed out that we were still in too much doubt as to the value of this agent as a cure for epithelioma to make it advisable to urge such an appropriation on the State.

**Report of Committee on Arrangements.**—Dr. CHARLES H. RICHARDSON in making this report, called attention to the clinical features of this meeting. Clinics would be held for the visitors at the various hospitals during the afternoons of the meeting, and opportunities would be afforded to visit the scientific and research institutions of the city.

**Report of Committee on Prize Essays.**—Dr. EDWARD D. FISHER reported for this committee that no essay had been presented in competition for the Merritt H. Cash prize and but one for the Lucien Howe prize. This was by Dr. M. J. Schoenberg, of New York and was entitled "Contribution to the Experimental Study of Ocular Anaphylaxis."

**The Report of the Committee Appointed to Consider the Question of the Prosecution of Illegal Practitioners.**—Dr. R. P. HIGGINS of Cortland presented this report, which was the result of a very careful investigation. They found the following facts to be true:

There were in most of the counties of the State, depending on their size and various local conditions, from one to several illegal practitioners. In many cases the local county society had procured indictments against these practitioners and the case had been brought to trial. In most of these cases, with the notable exception of the cities of New York and Buffalo, where the prosecution of these cases had been well organized, the defendants had been acquitted and the after effect of the verdict had been to establish them more firmly than ever in their practice. In rural or smaller communities local prejudice and feeling had been drawn upon and the defense had maintained that this was a free country and defendant was a poor fellow trying to earn an honest (?) living, and that the physicians had been trying to establish a monopoly of the healing art, and that many physicians' acts would not bear the light of investigation. In many of these cases the defense had endeavored to bring forward the claim that he had only done good, that he had cured cases pronounced incurable by the physicians, and that he had done no harm by his practice. It was just on these points that it seemed to the committee that successful prosecution could be brought. No matter what might be the technical violation of the law, unless evidence could be brought forward showing actual harm done by the defendant, prosecutions would be very difficult in the smaller communities. This could and should be done in every posible case, and instances of the harm done by these practitioners should be brought to the attention of the public in some forcible manner. It was suggested that the State Society through the State *Journal* could serve as a medium for spreading the information, and county boards of censors could be advised as to proper steps to be taken in prosecuting these cases and that the State Society, through its executive officers or through a standing committee for this purpose, serve as a bureau of information and tender its advice and counsel when requested, either in advice as to getting evidence in these special cases, or in counsel when these cases are presented for trial. This report was accepted.

**Report of the Counsel.**—JAMES TAYLOR LEWIS submitted this report. He stated that more actions had been begun during the past year than during any other year, and if certain years were selected more had been brought than during two years together. In all there had been fifty-seven actions brought. Thus it went without saying that the work of the counsel had been far greater than ever before. Only one case had been lost and that had been appealed. For years many physicians had settled their own cases and it was evident why the number of cases coming to the counsel of the Society was small; but now the knowledge of this defense having finally reached the great body of physicians in this State, and realizing the powerful influence for good represented by this organized malpractice defense there had been less and less of this settling of cases. The counsel felt certain that there would be a great reduction in the number of cases brought during 1914, because lawyers who were bringing these actions were becoming more and more discouraged. In no case of malpractice had any member of the State Society been called upon to pay money.

**Election to Honorary Membership.**—Dr. JOHN GEORGE ADAMI of Montreal, Canada, was elected to honorary membership in the Medical Society of the State of New York by unanimous vote.

**Election to Retired Membership.**—Dr. EDWARD GEORGE RAVE of Hicksville was unanimously elected to retired membership in the Society.

**Resolutions Adopted.**—Among the resolutions adopted by the House were the following: A resolution providing that the Committee on Public Health of the State Society form a standing committee to act in connection with the Council on Health and Public Instruction of the American Medical Association. A resolution providing for a committee which shall prepare a bill designed to raise the requirements of the medical practice law so that a high school diploma with 72 counts on the Regent's examination be required for entrance to a medical school, and that one year's work in chemistry, biology, and physiology be required for admission; these might be taken in the medical course, in which case five years should be required in the medical schools. Resolutions pointing out the increasing menace and burden of the mental defectives allowed to enter our port and urging the appointment of an efficient corps of examiners under the Public Health Service for the examination of immigrants. Resolutions providing for the appointment of a committee of two who should formulate a fitting memorial to Dr. Egbert Le Fevre, Dr. Joseph D. Bryant, Dr. Roswell Park, and Dr. Nathan Jacobson. Resolutions providing for the appointment of a commission to investigate the midwife problem in this State and to present a report at the next meeting.

**Place of Meeting.**—It was voted to hold the next meeting in Buffalo on April 27, 1915.

*Tuesday, April 28—Second Day.*

**Election of Officers.**—The following officers were elected for the ensuing year: *President*, Dr. GROVER W. WENDE of Buffalo; *First Vice-President*, Dr. MYRON B. PALMER of Rochester; *Second Vice-President*, Dr. S. W. S. TOMS of Nyack; *Third Vice-President*, Dr. ROBERT W. ELLIOTT of Willard; *Secretary*, Dr. WISNER R. TOWNSEND of New York; *Treasurer*, Dr. ALEXANDER LAMBERT of New York; *Chairman of Committee on Scientific work*, Dr. T. H. MCKEE of Buffalo; *Chairman of Committee on Public Health*, Dr. JOSHUA M. VAN COTT of Brooklyn; *Chairman of Committee on Legislation*, Dr. LEWIS K. NEFF; *Chairman of Committee on Arrangements*, Dr. ALBERT T. LYTLE of Buffalo; *Chairman of Committee on Medical Research*, Dr. FRANK VAN VLEET; *Delegates to the American Medical Association for two years*, Dr. DWIGHT H. MURRAY of Syracuse, Dr. J. W. FLEMMING of Brooklyn, Dr. WENDELL C. PHILLIPS of New York, Dr. J. C. MACEVITT of Brooklyn, and Dr. CHARLES H. RICHARDSON of New York; *Alternates*, Dr. OWEN E. JONES of Rochester, Dr. SAMUEL LLOYD of New York, Dr. M. M. LUCID of Cortland, Dr. A. W. BOOTH of Elmira, and Dr. W. E. BOWEN of Rochester, and Dr. J. R. KEVIN of Brooklyn.

**Presentation and Adoption of Resolutions.**—Resolutions were adopted providing for the appointment of a committee of three to be present at the convention on the revision of the Constitution of New York State to see that the interests of the profession were properly protected. . . . The following resolution was also adopted: *Whereas*, the object of the National Food and Drug Act as applied to drugs being specifically for the purpose of conserving the public health in relation to the standard of purity and quality, and *Whereas*, under the present construction of the law in relation thereto it is manifest that the purpose is wholly defeated by the proviso which admits of any standard, and *Whereas*, there could be only one standard of purity quality in medicines in order to safeguard the public health, *Resolved*, That we of the Medical Society of the State of New York use every effort so that there be but one recognized standard of purity and quality and that the one designated by the United States Pharmacopœia and the National Formulary.

---

GENERAL SESSION.

*Tuesday, April 29—First Day.*

THE PRESIDENT, DR. WILLIAM FRANCIS CAMPBELL, IN THE CHAIR.

**Address of Welcome.**—Dr. WILLIAM FRANCIS CAMPBELL made this brief address in which he extended a hearty welcome to all and hoped that the meeting would prove edifying as well as entertaining. He stated that a broad medical culture was not attained by staying at home and plying in the old groove. This had been recognized and the spirit of travel and of exchange of courtesy and work was abroad and was vitalizing the profession to a remarkable extent. No town had a monopoly of the genius of American Medicine, and thus they had gone from New York to Cleveland to cull the blooms on that fruitful vine and to find the leaven that would leaven the mass. In closing Dr. Campbell referred to the wealth of clinical material in the city and urged the visitors to take advantage of what was offered.

HONORABLE MARK M. MARKS, Borough President of Manhattan, in a brief address of welcome, spoke of his pleasant relations with physicians and said that in sending one his check he had always added "This is but a nominal acknowledgment of the care and worry you have had in my behalf; your service is one which money cannot repay." He then spoke of the altruistic spirit of the profession as typified by such men as Dr. Abraham Jacobi and Dr. Hermann Biggs, and said that the spirit of the day was to give rather than to receive. The emphasis in medicine today was being placed on the prevention rather than the cure of disease.

**The Kinetic System.**—Dr. GEORGE W. CRILE of Cleveland delivered the Address on Medicine, in which he formulated a theory which he hoped would harmonize a large amount of clinical and experimental data; supply an interpretation of certain diseases, and show that many and diverse causes produced the same end effects; to offer evidence that there was in the body a system evolved primarily for the transformation of latent energy into motion and into heat. This system the author designated the "Kinetic System." It did not directly circulate the blood, exchange oxygen for carbon dioxide, it did not perform the functions of digestion, urinary elimination or procreation, but it did indirectly play an important rôle in each. The principal organs which comprised the kinetic system were the brain, the thyroid, the suprarenals, the liver, and the muscles. After specifying the particular functions of each of these organs, the writer said that adrenalin alone, brain activity alone, and muscular activity alone were capable of causing the temperature to rise above normal. The functional activity of no other gland alone and the secretion of no other gland alone could cause a comparable rise in body temperature—that was, increased functional activity, and no active principle derived from the kidney, the liver, the stomach, the pancreas, the hypophysis, the parathyroids, the spleen, the intestines, the thymus, the lymphatic glands or the bones could *per se* cause a rise in the general body temperature comparable to the rise that might be caused by the activity of the brain or the muscles or by the injection of adrenalin or thyroid extract. When the brain, the thyroid, the suprarenals, the liver, or the muscles were eliminated the power of the body to convert latent into kinetic energy was impaired or lost. The author then offered evidence to show that an excess of either internal or external environmental stimuli might modify one or more organs of the kinetic system and that this modification might cause certain diseases. The amount of latent energy which might be converted into kinetic energy varied in different species; in individuals of the same species; in the same individual in different seasons; in the life cycle of growth, reproduction and decay; in the waking and the sleeping hours; in disease and in activity. The author then considered the reasons for some of those variations and the mechanisms which made them possible. If his thesis that men and animals were mechanisms responding to environmental stimuli was correct, and if the speed of energy output was due to changes activating the organs as a result of adaptive stimulation then they should expect to find physical changes in the activating glands during the cycles of increased activation. The facts were that most animals had breeding seasons evolved as adaptations to the food supply and weather. Hence there was in most animals a mating season in advance of the season of maximum food supply so that the young might appear at the season when food was most abundant. During the mating season the thyroid was known to enlarge materially though this increase in thyroid activity was probably no greater than the increased activity of other glands. Not only was there a seasonal rhythm in the rate of flow of energy, but there was a diurnal variation, the ebb was at night and the full

tide in the day time. In addition there were variations also in the rate of discharge of energy in the various life cycles of the individual. The young were evolved at higher speed for growth, so as the sooner to develop the power of self-protection. They must adapt themselves to bacteria, to food, to all the elements in their environment. The cycle of greatest kinetic energy ended with the period of reproduction. The secondary sexual characteristics might be developed at will, for example, by feeding thyroid products from alien species to the individual deprived of the thyroid. The author then considered the conversion of latent into kinetic energy in the production of heat. The question which arose at once was: Was there one mechanism for the conversion of latent energy into muscular action? What was the adaptive advantage of fever? In fevers there was a diminished intake of energy but an increased output of energy, hence the available potential energy in the body was rapidly consumed. This might be an adaptation for the purpose of breaking up the foreign protein molecules composing the bacteria. Thus the body might be purified by chemical combustion so furious that frequently the heat itself was destroyed. As to the mechanism which produced fever the writer postulated that it was the same as that which produced muscular activity. Muscular activity was produced by the conversion of latent energy into motion, and fever was produced largely in the muscles by the conversion of latent energy into heat. They should, therefore, find similar changes in the brain, the adrenals, the thyroid, and the liver whatever might be the purpose of the conversion of energy, running, fighting, emotions, or infections. As a result of excessive activity from whatever cause experimental evidence was adduced tending to show what part was played by the brain in the production of muscular and febrile action, and then the part played by the suprarenals, the thyroid, and the liver was discussed. To this end he had studied the brain cells in human cases of fever, in animals after prolonged insomnia, after the injection of toxins, gonococci, streptococci, staphylococci, bacilli of tetanus, diphtheria, and typhoid, of foreign proteins, indol, and skatol; of leucin and peptones. He had studied the brains of animals that had been activated in varying degrees up to the point of complete exhaustion by running, fighting, by rage and fear, by physical injury and by the injection of strychnine; the brains of salmon and the brains of electric fish, the brains of woodchucks in hibernation and after fighting; the brains of humans who had died from anemia, resulting from hemorrhage, from acidosis, from eclampsia, from cancer, and from other chronic diseases. They had studied the brains of animals after the excision of the suprerenals, of the pancreas, and of the liver. In every instance the loss of vitality, the loss of normal power to convert potential into kinetic energy was accompanied by physical changes in the brain cells. *The changes in the brain cells were identical whatever the cause.* The crucial question then became: "Were these constant changes in the brain cells the result of work done by the brain cells in running, fever, emotion, etc.?" In cross circulation experiments he had found that the brain cell changes were not due to waste products or to metabolic poisons. He found that in the production of muscular action and of fever there were brain cell changes which showed a quantitative relation to the temperature changes or to the muscular work done. He had observed that under deep morphinization the febrile response or the muscular work done was either diminished or eliminated and that the brain cell changes were correspondingly diminished or eliminated. He found also that brain cell changes and muscular work followed electrical stimulation alone. He therefore concluded that brain cell changes were work changes. The writer then considered the other organs of the kinetic system in their relation to muscular activity, to emotion, to consciousness, to hibernation and to heat production. It was shown that brain and suprarenal activity went hand in hand. It was further shown that there was an interdependent relation between the brain, the suprarenals, and the liver. Histological studies were made of every organ in the body, in animals after they were subjected to a long period of wakefulness and only these three organs showed histological changes. With these three kinetic organs they also associated the "furnace," the muscles, in which the energy provided by the brain, the suprarenals, and the liver plus oxygen fabricated into heat and motion. He then showed that none of these organs had the power to change the rate of discharge of energy, but that the thyroid presided over this function. In other words it was the pace maker. The effect of the output of energy of impaired or lost function of each of the several links in the kinetic chain was then discussed and it was shown that if the brain was impaired it could not stimulate other organs to the conversion of energy into latent heat or motion, but in these cases one found weakened muscular and intellectual power. In such destructive lesions of the suprarenals as Addison's disease one of the cardinal symptoms was a subnormal temperature and impaired muscular function power. When the function of the liver was impaired by tumors, cirrhosis, etc., then the entire energy of the body was correspondingly diminished as evidenced by the gradual loss of efficiency which finally reached the stage of asthenia. It had been observed that if the muscles were impaired by long disuse, then the range of production of both heat and motion was below normal. When the thyroid was impaired as in myxedema, one of the cardinal symptoms was a persistently subnormal temperature, and subjects of myxedema showed but feeble febrile response and readily succumbed to infection. If our conclusions were sound then in the kinetic system was found the explanation of many diseases, and having found this explanation in time they might find new methods of combatting them. The author then considered what he termed the kinetic diseases. When the kinetic system was driven at an overwhelming rate of speed as by severe physical injury, intense emotional excitement, perforation of the intestines, the pointing of an abscess into new territory, or by the sudden onset of infectious disease, by an overdose of strychnine, by foreign proteids, etc., the result was clinically designated shock, and, according to the cause, termed traumatic shock, toxic shock, etc. The essential pathology of shock was essentially the same whatever the cause and whenever any one link in the kinetic chain was unable to bear the strain, the balance was destroyed. If the brain was the weakened link then neurasthenia, nerve exhaustion, or even insanity followed. If the thyroid could not endure then that organ underwent hyperplasia, which might result in colloid goiter or exophthalmic goiter. If the suprarenals could not bear the strain the cardiovascular disease might develop. If the liver, then death from acute acidosis might follow, or if the neutralizing effect of the liver was only partially destroyed then the acidity might cause Bright's disease. Over activation of the kinetic system might cause glycosuria and diabetes. Identical physical and functional changes in the organs of the kinetic system might result from intense continued stimulation from any of the following causes: Excessive physical exercise, worry or anxiety, athletic exercise, chronic infections, such as oral sepsis, tonsilitis, adenoids; chronic appendicitis, chronic cholecystitis, colitis, skin infections, emotional strain, intestinal autointoxication, excessive intake of proteid food, business or professional strain. In this hypothesis one found the reason why cardiovascular diseases might be caused by chronic infection, by acute intestinal autointoxication, overwork, or emotional excitement. The problem was whether this theory would stand the test of clinical experience; of controlling the protein disease bred in the stress of daily life. The force of the kinetic stimuli might be broken at the thyroid by dividing the nerve supply, reducing the blood supply, or by partial excision. They already had the shockless operation, the surgical treatment of Graves' disease, the control of shock and the acute infections by overwhelming morphinism.

## NEW YORK NEUROLOGICAL SOCIETY.

*Stated Meeting, Held January 6, 1914.*

THE PRESIDENT, DR. SMITH ELY JELLIFFE, IN THE CHAIR.

**A Case of Traumatic Epilepsy Cured by Operation.**—Dr. WILLIAM M. LESZYNSKY presented a man, thirty years old, with a negative family history and whose personal history was uneventful up to the age of six years. At that time he fell from a height, receiving a compound, comminuted fracture of the skull over the right temporo-parietal region. He was taken to a hospital, where he was treated surgically, a section of the bone being removed, and when he returned home, a few weeks later, he was apparently free from all symptoms. A few months later he began to attend school, and ultimately became a bookkeeper. At the

age of twenty-one, fifteen years after the receipt of his injury, he began to develop epileptic convulsions. The attacks were at first infrequent, and always began with a convulsive movement of the left hand, gradually becoming general. For five years he averaged about one attack a month, but they gradually became more frequent and severe, and when Dr. Leszynsky first saw the patient, nearly four years ago, he had recently had four severe attacks in a single night. Upon examining the cranium, the presence of adhesions over the site of the old wound were suspected, and an early operation was recommended, and this was done by Dr. Henry Roth at the Lebanon Hospital on May 23, 1910. It was then found that the skull, the dura and pia mater and the cortex were matted together in one mass. After some difficulty the cortex was freed and covered with a piece of Cargile membrane and the wound was then closed. The patient's operative recovery was good, and he left the hospital shortly afterwards. Three years and eight months had elapsed since the operation, and the man had never had an epileptic convulsion since that time. His treatment had been purely hygienic, and he had never received any sedative drugs.

Dr. Arthur C. Brush, of Brooklyn, said the theory promulgated by the late Dr. Ira Van Gieson a few years ago that the epileptic seizures were the result of a wedge-shaped piece of tissue producing irritation of the cortex did not hold good in this case, as nothing was done here but to separate the adhesions and insert a piece of Cargile membrane. Here we either had to accept the fact that the epilepsy was cured by the surgical operation or else that the epilepsy was not due to the injury at all. The fact that the convulsive movements began in the left hand and were followed by unconsciousness pointed to the Rolandic area.

Dr. Leszynsky, in closing, said the character of the attacks was always the same, invariably beginning in the left hand, extending up the arm and over the rest of the body, with almost immediate loss of consciousness. The patient never had any *petit mal* attacks. The attacks occurred both during the day and at night, and were purely Jacksonian in the beginning.

A Case of Multiple Sclerosis.—Dr. S. P. Goodhart presented a girl, twenty-four years old, with a negative family history, who seven years ago began to complain of peculiar burning sensations in the palms and soles. Finally, this paresthesia extended to the upper and lower extremities, giving her the sensation, as she described it, as though the extremities were enveloped in gloves. This disappeared, and was followed by a flaccid paralysis of the lower extremities, which practically became complete. At the end of three months she began to improve and three months later the paralysis had entirely disappeared. She then remained well until last July (1913), when she began to suffer from weakness in the left upper extremity, and extending very gradually to the corresponding lower extremity. The eye grounds at this time suggested some change in the disks. In the course of a short time this paralysis, which followed a very suggestive anatomical distribution, was accompanied by a tremor, and the case now presented a typical picture of multiple sclerosis, which was confirmed by the eye findings. There was an absence of the abdominal reflex; a marked Babinski was present on the left side, less marked on the right. The patient had also developed a peculiar spasm of the left hand. There was nystagmus on convergence. The Wassermann was invariably negative.

Epilepsies and Psychoanalysis: A Query.—Drs. Smith Ely Jelliffe and Frank M. Hallock presented this paper.

Dr. Jelliffe, preliminary to the presentation of a patient bearing on this subject, said we knew so little about the dynamic factors in the causation of the epileptic discharge, particularly in the so-called true or idiopathic type of epilepsy, where we had no antecedent history, and objective neurological examination left us at a loss, that he took occasion to ask Dr. Hallock to investigate some of these cases, more particularly in relation to their complex reactions and psychic disturbances, in the hope of eliciting some facts that might be pertinent to or have some bearing upon the particular type of energy discharge. The class of patients he had in mind were those in which the seizures had come on at about the ages of eleven, twelve, or thirteen, more or less coincident with the awakening of the puberty influences. Even from the time of the early Greek writers, coitus had been described as a minor epileptic attack, and the motor manifestations of the epileptic discharge were so striking as to suggest the possibility of such a relationship. Possibly, and the subject is presented to-night in the form of a query, this apparently motiveless discharge of energy may depend upon certain psychogenic factors that were worthy of investigation. We know that during the night, when the usual avenues of energy dissipation are not open, that epileptic attacks are more frequent than during the daytime. It is a familiar fact that in institutions where large numbers of epileptic individuals are grouped, interference with the regular routine employment of the patients, such as that caused by a rainy day, a stormy day, Sundays and holidays, is coincident with an increase in the number of attacks: such attacks occur more frequently when the patients are not discharging energy in normal ways. It might be possible that the rigid application of the libido theory with the psychoanalytic study of the distribution of energy and the introversion of energy might offer a field in which an explanation for certain forms of epileptic discharge might be formulated.

Dr. Frank M. Hallock said this case was presented very early in the course of the psychoanalysis. The patient was an epileptic boy, seventeen years old, who came to Dr. Jelliffe's clinic at the Post-Graduate Hospital on October 15, 1913. His family history was negative. The epilepsy began at the age of eleven years, the attacks occurring about twice a month, without prodromata. They began with twitching of the right hand and occurred only during sleep, lasting from two to twenty minutes. During the attacks the patient frequently bit his tongue. There were occasional semiconscious states, with staring and dreamy states, lasting a few seconds or minutes. Occasionally, the boy heard voices; sometimes it was part of a prayer, etc. He also complained of certain insistent words that troubled him for several days. The boy was unable to work on account of his convulsions; he feared that work might aggravate them, although they never occurred during his waking state. He also had a tendency to hoboism, and had once beaten his way from Springfield, Ill., to St. Louis on a freight train. He had made attempts to hypnotize himself by staring into a mirror until he lost his equilibrium, and staggered across the floor. He said he had also tried "stunts" with his eyes to make them come together by holding his finger near the nose, in order to make each eye independent of the other. He had done this half an hour at a time. Inquiries into the boy's sexual life elicited the fact that masturbation began through the instruction of other boys at the age of twelve and a half, but was stopped by his uncle six months later. Two years ago he again began to masturbate, and continued the practice for several months. Other sexual experiences had been slight, and there had never been any seminal discharge. The boy's environment had been a difficult one. When he was a small child he liked his father, but now he looked upon his as too much of a religious fanatic. This dated back to about the age of ten. "I began," he said, "to read Darwin, but my father was steeped in his old orthodox beliefs and we clashed. He has beaten me plenty of times, ever since I can remember." He was also frequently beaten by the Rabbi, to whom he was sent for religious instruction. Of his mother, he said: "I like her pretty fair. She is a little better than father. Because he doesn't like me, she does." Of his sister, fifteen years old, he said: "She is my father's pet, and I got into many scrapes on her account." The patient had occasional dreams of sexual intercourse with this sister. He had no girl friends. The patient had many dreams, some of them very intricate. They were full of his struggles with his father. After one of these he awoke, his father shaking him vigorously in order to awaken him, asking what he was yelling about, and evidently fearing an impending fit. As the child advanced in years he met with decided rebuffs. He sought expression for his love-nature and found his father in the way. As a young child he knew the world only through father and mother, and it seemed to him to be a pretty tough world. Rather than make any further effort toward understanding his love-life, which demanded expression in some form, he retired to the cradle—to the memories of his infancy and childhood. He dreamed of a nest in his mother's arms, where he would be loved as he was when a baby. One day, after having a fit, he was asked how he felt, and he replied: "I feel like a baby three or four years old. When I am well I beat my own way and do as I like, but now I do whatever my mother tells me. She treats me better than she does the other children. To-day I asked her why, and

she said because of my illness." He had thus succeeded in his unconscious object of drawing his mother's sympathy and attention by means of his fits, thus feeling himself once more in her care, as he was when a baby. Dr. Hallock said the analysis of this case would be continued, because, with the understanding of the nature of his conflict, the patient's attitude of mind toward life had already changed. He expressed himself as feeling different and better. The struggle with his environment was not so keen and his dreams had already shown some change in the direction of an understanding and control of his conflict.

Dr. C. P. Oberndorf asked if the more important signs of the classical epileptic attack, such as the abolition of the corneal and light reflexes while the patient remained unconscious, involuntary evacuation of the bowels and bladder, and the Babinski sign immediately following the convulsion had been recorded in this case.

Dr. Hallock could not answer Dr. Oberndorf's questions, as he had never seen the boy during an attack.

Dr. Oberndorf said that without an accurate examination during the attack it was impossible to distinguish between epilepsy and the convulsive manifestations of hysterical states, or some of the lapses seen in dementia præcox. In one case of convulsive attacks, apparently of psychogenetic origin, which he had observed, there was voiding of the bladder, and in another case, in a girl of twelve, the attack culminated in an orgasm. In both instances the attack seemed to be a substitution for masturbation. In the case just presented there was no evidence to warrant the assumption that the attacks, whether hysterical or otherwise, were dependent on either the conscious or unconscious psychical life of the patient, nor had any analysis of the hallucinations been attempted.

Dr. Jelliffe said the attacks were accompanied by biting of the tongue and involuntary evacuations of the bowels and bladder, and he had no doubt that they were of the major epileptic type.

Dr. I. Abrahamson said he could see no possible connection between the epilepsy in this case and the psychoanalysis. Many of the dreams that had been reported by Dr. Hallock appeared to be due to suggestions received from the examiner.

Dr. Hallock said that what was apparent on the surface of a dream was not its real meaning, which was something quite deeper. While his close association with the patient might bring out something, it would have nothing to do with the true meaning of the dream.

Dr. Jelliffe said that while this work was still in an experimental stage he thought Dr. Hallock had gone quite far enough to show that in this particular case the theoretical importance of the Œdipus complex was demonstrated, and that possibly the motor discharge was in response to the psychogenetic factor of hate to the father and incestuous phantasies regarding the mother. We should not lose sight of the fact that we were merely discussing a form of energy distribution which is described under the symbol epilepsy.

**The Intensive Treatment of Syphilis of the Nervous System by Neosalvarsan, Intravenously, and Mercury by Injunction: A Preliminary Report.**—Drs. Frederick Peterson and J. W. Stephenson presented this communication. (See p. 786.)

Dr. J. Ramsay Hunt, after referring to the very encouraging results obtained in the cases reported by Dr. Stephenson, said that Ehrlich had lately recommended the combined use of salvarsan and mercury in obstinate cases. A course of treatment with salvarsan, then, after a brief intermission, a course of treatment with mercury, or the mercury might precede treatment with salvarsan. In a recent paper Wechselmann had attributed a certain number of deaths from salvarsan intoxication to the preliminary use of mercury; he claims that the mercury produces a mild form of nephritis, or renal disturbance, so that when the salvarsan is given the kidneys are incapable of eliminating the arsenic, and that a second injection under such conditions may result in serious symptoms of intoxication. It was well to keep this possibility in mind, Dr. Hunt said, in connection with the intensive treatment, as outlined by the reader of the paper. We know that the kidneys are an important factor in elimination, and during such a course of treatment as this the renal secretion should be frequently examined, preferably daily, and at the slightest indication of disturbance further medication should be postponed and every precaution should be taken to guard against untoward results. Dr. Hunt said he had seen two cases of very severe intoxication from salvarsan, both following the second injection. In both instances slightly less than the usual dose was employed, and the full interval of one week was allowed to elapse after the first injection. In one of the cases a severe myelitis developed, and in the other there was a general intoxication, with jaundice. Both were most severe, and, in the acute stage, alarming cases. While the results obtained in the series of cases reported by Dr. Stephenson were most encouraging, both from a serological and clinical standpoint, they should not blind us to the possible danger of pushing the medication in these patients.

Dr. Leszynsky said that in one of the cases reported by Dr. Stephenson he spoke of giving one-sixth of a grain of mercury, presumably the bichloride, following which the Wassermann in both the blood and cerebrospinal fluid became negative. It was an open question, Dr. Leszynsky said, whether the serological reactions were changed by the mercury or the salvarsan, and, personally, he would be inclined to depend on the action of the former, which was safer than salvarsan. The speaker said that in a number of cases he had used potassium iodide in increasing doses coincident with injection of neosalvarsan, without untoward results.

Dr. Abrahamson said that at the Mt. Sinai Hospital, in the service of Dr. B. Sachs, they employed an intensive method of treating severe cases of cerebrospinal syphilis, but the treatment was carried over a longer period than that described in the paper. In cases with a doubtful and negative Wassermann, they give a provocative injection of salvarsan to bring out a positive reaction. In connection with this general subject, the speaker said, the question naturally arose, what did a serological examination mean? Personally, he did not believe that the result of an examination of the cerebrospinal fluid indicated definitely the degree of the infection. Such a presumption was too often contradicted by the actual findings. On the one hand, they saw serious paretic and tabetic cases with mild serological findings, while on the other hand, patients with very slight symptoms often gave very positive blood and cerebrospinal findings. The important factors were the symptoms presented by the patient. They deserved more consideration than a negative or positive Wassermann in the blood or fluid; the effect of treatment on the biological findings was very important. Dr. Abrahamson said their results with general paresis had not been as favorable as some of those reported by Dr. Stephenson, and they had not succeeded in rendering the fluid of many general paretics negative. These had proven the most obstinate of all their cases, much more so than the tabetics. He did not believe that the biological examination was definitely diagnostic between taboparesis and general paresis.

Dr. Goodhart, replying to Dr. Hunt, said he did not think it was the mercury that brought about the disturbance of the renal function, which, in turn, was responsible for the subsequent salvarsan intoxication. We knew that salvarsan was given to syphilitics by men in other lines than neurology with comparatively little regard to organic disturbance, such as heart lesions, etc. Personally, he was rather inclined to attribute the untoward results that had been reported to the combined treatment. When salvarsan and mercury were administered at the same time, it was quite possible that a poisonous compound was thus generated.

Dr. H. Goldenberg said that in his remarks he would limit himself to a discussion of the statement of Wechselmann, quoted by Dr. Hunt, that some of the fatal results which had been reported were due to the combination of salvarsan and mercury. Without any intention of trying to detract from the credit of Wechselmann for his work in this field, we should not lose sight of the fact that he had not been entirely consistent, and had changed his mind repeatedly on this point. At first, he attributed the fatalities to the so-called "Wasserfehler," and now he thought these were due to the mercury which had been combined with the salvarsan. Dr. Goldenberg said that from the very beginning of the salvarsan era, he had made it a rule, at Mt. Sinai Hospital, to combine the salvarsan with mercury injections. He had had two deaths which were due not to the mercury, or to the combination of the mercury and salvarsan, but purely to the salvarsan. The first was one of his very early cases; in fact, his first case of intravenous injection. The patient was an adult with mucous patches, who had contracted a chancre ab
year before. He left the hospital five days aft
injection, went on a debauch the same night, a
readmitted two days later. He was then irr

became maniacal, and died a week later under the symptoms of a hemorrhagic encephalitis. The second case was that of a girl of fifteen, with lesions on the vulva, due to an acquired infection. She had received one salvarsan injection without untoward symptoms. Two weeks later she received a second injection of 0.4 gram, which was followed by a rise of temperature, a transitory erythematous rash, jaundice, multiple neuritis, with ulcerations in the mouth, at the base of the tongue and on the epiglottis. She died with the clinical picture of an acute yellow atrophy of the liver, seventeen days after the second injection. The so-called Herxheimer reaction, following immediately, sometimes while the patient was still on the table, or, subsequently, the symptoms consisting of flushing of the face, watery eyes, intense headache, swelling of the mucous membranes of the mouth, abdominal cramps, etc., had recently been explained by Milian, a French writer, as being due to a dilatation of the blood-vessels caused by the arsenic. In a number of cases where he had previously observed this complex of symptoms he was able to prevent them after subsequent injections by the previous intramuscular administration of adrenalin. Neurorelapses were not longer seen in his service. Dr. Goldenberg said, since the patients were given sufficient salvarsan treatment. They were due to syphilis, and not to salvarsan.

Dr. Hunt thought that Wechselmann's discovery of the "Wasserfehler" was a most valuable contribution to the technique of the administration of salvarsan. It was a step in the right direction toward the perfection of that technique, and the same could be said of his more recent work in attributing the possibility of salvarsan intoxication to the deleterious action on the kidneys of a preceding course of mercury. This, the speaker thought, could scarcely be regarded as a change of mind on Wechselmann's part. It was certainly of the first importance that every contributing factor in the production of unfavorable results, both in the technique of administration and the selection of cases be carefuly analyzed, and such factors, when determined, eliminated. It could hardly be questioned that ignorance of these factors in the early period of the salvarsan treatment and inattention to them in the later was largely responsible for the fatalities and many of the untoward results that have occurred.

Dr. Goldenberg said he did not wish to be misunderstood in his remarks as criticising Wechselmann, who was a pioneer in this work. He only spoke of the apparent change in the views of that authority as to the cause of death following the administration of salvarsan. Personally, Dr. Goldenberg said, he had given salvarsan in a number of cases of supposed syphilitic nephritis not only without injurious results, but with great benefit to the patient.

**The Neural Atrophy of the Small Muscles of the Hand, Without Sensory Disturbances.**—Dr. J. Ramsay Hunt referred briefly to the two types of neural atrophy of the small muscles of the hand, without sensory disturbances described by him in previous communications:

(1) A hypothenar type, from compression neuritis of the deep palmar branch of the ulnar nerve; (2) a thenar type, from compression neuritis of the thenar branch of the median nerve. The author stated that one of the chief points of clinical interest of these two types of neural atrophy of the small muscles of the hand without sensory disturbances lay in their resemblance to and possible confusion with the atrophy of the hand muscles of spinal cord origin, viz., the Aran-Duchenne type of progressive muscular atrophy, the early stage of amyotropic lateral sclerosis beginning in the hand musculature, and the various types of subacute and chronic poliomyelitis of syphilitic origin, in which the lesions originated in, or were more or less restricted to the lower segments of the cervical cord. Of special importance was the so-called tephromalacia anterior described by Marie and Foix, in which the atrophy of the anterior horns, limited to the 8th cervical and adjacent portion of the 7th cervical and 1st dorsal segments of the cord, was produced by a vascular lesion of syphilitic origin. (Endarteritis and periarteritis without thrombosis.)

(1) The *hypothenar type* of neural atrophy was characterized by a complete paralysis, with consecutive atrophy and reactions of degeneration in all the muscles of the hand supplied by the ulnar nerve. (The hypothenar, interossei, abductor pollicis, and inner head of the flexor brevis pollicis.) There were no objective or subjective disturbances of sensation in the distribution of the ulnar nerve. The ulnar flexion of the wrist was preserved, as was also the function of the palmaris brevis. The motor branch to this small subcutaneous muscle passing in the superficial palmar, which is sensory; the deep palmar is partly motor in function. The preservation of this small motor branch to the palmaris brevis and of the sensory functions showed that the compression lesion was situated in the deep volar branch, after the division of the nerve at the level of the pisiform bone. Just after this division the deep palmar branch passed between the tendinous origins of the abductor minimi digiti and the flexor brevis minimi digiti, to beneath the hook of the unciform bone. The compression neuritis, therefore, by a process of exclusion, must take place in this section of the deep palmar branch.

Report of a case: The patient was a man of thirty, by occupation an ironer and presser of clothes. He denied lues and gave no history of alcohol or lead intoxication. For the past six months he had suffered from weakness of the right hand, with gradually increasing atrophy. In spite of this he had continued his occupation. He had no pain and no paresthesiæ in the distribution of either the ulnar or median nerves. There was complete paralysis, with considerable wasting, of all the hand muscles supplied by the ulnar nerve, with complete reactions of degeneration. The ulnar flexion of the wrist and the function of the palmaris brevis were preserved. Sensation was perfectly normal to touch, pain and temperature, and the deep sensibility was preserved. The atrophy and paralysis were strictly limited to the ulnar distribution in the hand, and the hand had somewhat the attitude and appearance of the *main en griffe*. No fibrillation was present. There was no tenderness on pressure along the ulnar nerve, but deep pressure at the pisiform bone was slightly tender. The pupils were equal and reacted normally. All the tendon reflexes of both upper and lower extremities were normal in intensity, and were equal on the two sides. The skin reflexes were normal. The plantar reflex gave a flexion response on both sides. An *x*-ray examination for cervical ribs was entirely negative. There was no lead line on the gums, and the Wassermann reaction was negative. The urine was normal. Lumbar puncture was not permitted.

(2) The *thenar type* was characterized by paralysis and reactions of degeneration, with atrophy of all the small muscles of the thenar eminence supplied by the median nerve. There were no subjective or objective sensory disturbances in the distribution of this nerve. The compression lesion in this type takes place beneath the anterior annular ligament, where the thenar branch, a purely motor nerve emerged before dividing into the muscular branches to the abductor pollicis, the opponens pollicis and the outer head of the flexor brevis pollicis.

Report of a case: The patient was a man, forty-nine years old. He denied lues, had used alcohol in moderation, and gave no history of lead intoxication. By occupation he was a general houseworker, sweeping, scrubbing, and washing floors and polishing brass. This patient, Dr. Hunt said, had been under his direct observation for a year, presenting himself originally for a weakness of the left thumb, with wasting of the muscles in the thenar region. This had appeared a few weeks previously without pains or paresthesiæ. During the entire period of observation he had had no subjective sensations in the distribution of the median nerve. The paralysis and atrophy were confined to the thenar muscles supplied by the median nerve. The function of the abductor pollicis and the inner portion of the flexor brevis pollicis were preserved. There were complete reactions of degeneration in all the thenar muscles supplied by the median nerve; all the other small muscles of the hand were normal both in power and electrical reactions. No fibrillations were noted in the atrophic area. There were no objective disturbances of sensation in the right upper extremity, and the median distribution was entirely normal to touch, pain, and temperature. There was no tenderness along the course of the median nerve. The urine was normal. The *x*-ray showed no cervical rib. There was no lead line on the gums. The pupils were unequal, the right being greater than the left; both pupils were rigid to light, and the left only reacted to accommodation. The supinator, biceps, and triceps jerks were equal on both sides, and not exaggerated. The jaw jerk was present. The knee jerks were unequal, the right being less active than the left. Both Achilles jerks were present and equal. Plantar reflex normal. For the

past seven months the patient had complained of mild, lancinating pains in the legs and chest, with slight vesical trouble. No crises; no diplopia. A mammary zone of hypalgesia and analgesia was demonstrable. The Wassermann reaction was negative. Spinal puncture was not performed. Diagnosis, *incipient tabes* and the *thenar type of neural atrophy.*

The clinical diagnosis of incipent tabes in this case was based upon the Argyll-Robertson pupil, lancinating pains, unequal knee jerks, vesical disturbance, and a mammary zone of hypalgesia, a group of symptoms which makes such a diagnosis practically certain. The existence of parasyphilis in conjunction with atrophy of the thenar eminence suggested, first of all, a myelopathic origin, developing upon the basis of an old syphilis. This interpretation, the speaker said, he would exclude in the case under consideration for the following reasons: The paralysis was of rather rapid onset, and was definitely limited to the muscles supplied by the thenar branch of the median nerve. The reactions of degeneration were complete five weeks after the onset of symptoms, and were, as they are at the present time, definitely limited to the median nerve distribution of the hand. After a year's observation, there had been no extension of weakness or atrophy to other muscle groups of the hand. At no time had fibrillations been noted. The process had remained definitely limited to the distribution of the thenar branch of the median nerve on the left side.

The author believed that such affections as progressive muscular atrophy and chronic and subacute poliomyelitis could be excluded by reason of the strict limitation to a neutral distribution and the absence of progression and other symptoms indicating spinal cord involvment.

The tephromalacia anterior, as described by Marie and Foix, could also be excluded with equal certainty by reason of the comparatively acute onset of the symptoms and the strictly neutral distribution. In Marie's two cases of tephromalacia anterior of syphilitic origin, with autopsy, the lesions were bilateral, affecting both hands, although predominating in one, and there was a diffuse atrophy of the small muscles of the hand, and not limited to a definite neural distribution, as in the two groups of cases described by Dr. Hunt. The similarity may be great, however, as Marie insisted on the non-progressive tendency and the strict limitation to the small muscles of the hands. That the lesion of tephromalacia should be so limited was in itself interesting and peculiar, but that this limitation should assume a persistently neural character and distribution, as in the thenar and hypothenar types of neural atrophy of the small muscles of the hand, was from the very nature of the lesion scarcely conceivable.

In a recent communication before the Société de Neurologie de Paris, November 13, 1913, Marie and Foix recorded a case of double thenar atrophy, with autopsy, in which the spinal cord was found normal, and a compression lesion of the median nerve was demonstrated beneath the annular ligament of the wrist, which was confirmatory of the localization and nature of the lesion which the speaker said he had assigned in his original communications on this subject.

Dr. Abramson said that some years ago he showed two cases of bilateral symmetrical atrophy of the flexor brevis pollicis. The patients were presented at one of the meetings of this Society. He saw one of those patients recently, and there had been no change in his condition.

Dr. Goodhart said it was rather difficult to conceive how a lesion restricted to the 7th or 8th dorsal segment of the cord could produce such a selective action on certain muscless of the hand. Stewart and others recently reported cases where an atrophy and paralysis of certain muscles of the hand were traced to the presence of a cervical rib. The speaker said that he had reported similar cases. In one of them, double false ribs were described in one patient. The initial symptoms were atrophy of the interossei, and the diagnosis of progressive muscular atrophy had been previously made. Removal of both ribs arrested the progress.

Dr. Hunt, in closing, said that in his second case the *x*-ray had shown no evidence of the presence of a cervical rib. Of course, there were many lesions along the entire course of the peripheral neurones of the upper extremity which might produce these localized hand atrophies, and all such possible etiological factors should be borne in mind. The statements made by Marie and Foix in regard to the arterial changes observed in their cases were based on very thorough pathological studies. These vascular lesions were of specific origin, with a resulting atrophy and loss of substance of the anterior horns, with complete preservation of the white substance of the cord. That the tephromalacia should be so limited in a syphilitic vascular lesion is indeed strange, and the authors were unable to offer any explanation for this peculiar predilection for the lower cervical regions, and its limitation to one or two segments of the cord. Therefore, in the interpretation of non-progressive atrophy of the small muscles of the hand, without sensory disturbances, two distinct conditions must be borne in mind, the tephromalacia anterior and the thenar and hypothenar types of neural atrophy.

# State Medical Licensing Boards.

## STATE BOARD EXAMINATION QUESTIONS.

### Kentucky State Board of Medical Examiners.

*December* 11-13, 1913.

(*Concluded from page* 736.)

#### SURGERY.

1. (*a*) Give differential diagnosis between orchitis and epididymitis. (*b*) Give causation.
2. How would you reduce dislocation of the shoulder, (*a*) acute, (*b*) chronic?
3. Give differential diagnosis between fracture and dislocation of the hip.
4. Give method of reduction of dislocation of hip.
5. Give (*a*) diagnosis and (*b*) pathology of gastric ulcer.
6. (*a*) Under what circumstances would you advise operation for inguinal hernia? (*b*) What anatomical structures would be gone through?
7. Give (*a*) pathology, (*b*) diagnosis, and (*c*) indications for operation in empyema.
8. Give symptoms, diagnosis, and indications for operation in chronic prostatic hypertrophy.
9. What would make you decide when to advise operative measures in obstruction of the bowels?
10. (*a*) Define, (*b*) give pathology, and (*c*) precautions against surgical shock.

#### OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

1. Give the symptoms and etiology of marginal blepharitis.
2. Give the symptoms, etiology, and complications of iritis.
3. Give the differential diagnosis between conjunctivitis and iritis.
4. Tell us what you know of dacryocystitis.
5. Give Politzer's and Valsalva's methods of inflating the Eustachian tube and tympanum.
6. What ear symptoms would you expect in fracture of the base of the skull?
7. Give the ear complications that might possibly result from tonsillitis.
8. Give symptoms and etiology of edema of the glottis.
9. Give etiology of differential diagnosis of tuberculosis of the larynx.
10. (*a*) Describe the instruments used and (*b*) indications for intubation.

#### HYGIENE, MEDICAL JURISPRUDENCE, MENTAL, AND NERVOUS DISEASES.

1. Give period of incubation for scarlet fever, mumps, and measles.
2. (*a*) What is uncinariasis and (*b*) what is the prophylaxis?
3. (*a*) What is meant by occupational diseases? (*b*) Name four of the most common kinds. (*c*) How may they be prevented?
4. (*a*) Give the diagnosis and symptomatology of herpes zoster. (*b*) What are the characteristics of syphilitic eruptions of the skin?
5. Under what conditions is the induction of an abortion legally justifiable?
6. (*a*) Define a poison and (*b*) name five of the most common ones.
7. (*a*) How would you diagnose an impacted stone in the right ureter and (*b*) from what other conditions is it to be differentiated?
8. What is the clinical significance of acetone and diacetic acid in the urine?

9 What is meant by (*a*) Babinski's sign, (*b*) Stellwag's sign, (*c*) Kernig's sign?

10. Give differential diagnosis of tuberculous meningitis.

## ANSWERS.

### SURGERY.

1. In *epididymitis*, the swelling is elongated and is situated at the back of the testicle, and the latter can be felt of its usual size at the upper and anterior part of the swelling.

In *orchitis* the swelling is globular, and the enlargement and tenderness are most pronounced at the front and sides; the tunica vaginalis is filled with fluid; fever may be present.

*Epididymitis* may be due to gonorrhea, stricture, catheterism, some operation on the prostatic urethra.

*Orchitis* may be due to mumps, traumatism, cold, wet, rheumatism, gonorrhea.

2. *Recent dislocation of the shoulder.* Kocher's method of reduction is: to flex the forearm, press the elbow to the side, rotate the arm outward. Bring the arm forward and upward to a right angle with the body, then rotate inward, while the elbow is brought down over the body so that the fingers sweep the opposite shoulder.

"In trying to reduce an *old dislocation* give ether, make movement to break up adhesions, and persist in making these motions until the head of the bone is felt to move; then try at once to reduce by manipulation or extension and counter-extension, not waiting for two days, as some suggest. If the head of the bone cannot be made to move the Dieffenbach plan has been advised, which is to cut the tense restraining bands with a tenotome. Lord Lister, being much impressed with the danger inevitably linked with forcibly dragging old dislocations into place, prefers to cut down and restore the bone, employing, of course, the strictest asepsis, and surgeons in general have adopted this view. In some old dislocations excision of the head of the bone is the proper operation." (Da Costa's *Modern Surgery.*)

3. In fracture of the neck of the femur, the head of the femur will be found in the acetabulum; in dislocation, the acetabulum will be empty, and the head of the femur will be found elsewhere, *e. g.* on the dorsum of the ilium. In the fracture, crepitus *may* be elicited; in the dislocation, never. In the dislocation, there is inversion and a fixed position of the limb, both of which are absent in fracture. In fracture there is shortening and outward rotation.

4. In *backward dislocations:* "Flex the knee and thigh in position of adduction. Abduct the thigh and evert simultaneously. Bring the leg down straight. Lift up, bend out, roll out. Direct traction of the thigh forward in a line at right angles to the body." In *forward dislocations:* "Thigh is flexed in a position of abduction. Abduct the thigh and then invert it. Bring the thigh down straight. Lift up, bend in, roll in." (*Synopsis of Surgery.*)

5. For *diagnosis* of gastric ulcer, see ETIOLOGY AND PHYSICAL DIAGNOSIS, Question 10.

*Pathology:* "Peptic ulcers may be single, but are more often multiple. They are commonly situated in the lesser curvature and the posterior wall of the stomach, near the pylorus; occasionally they are found at the fundus or at the cardiac end. They vary in diameter from a few millimeters to three or five centimeters. Their shape is characteristic in that they have sloping edges giving them a funnel-form, with the apex toward the muscular coat. The edges may be irregular and rough, but are often, especially in older ulcers, quite smooth and rounded. Two dangers are always imminent, hemorrhage and perforation. Constant oozing of blood may be due to erosion of the surface, and larger hemorrhages may result from ulceration of one of the larger arterial branches of the stomach. Perforation is less common than hemorrhage. When the ulcer is situated posteriorly perforation is prevented by adhesions attaching the stomach to the head of the pancreas or other structures. When the ulcer is in the anterior wall perforation is more liable to take place. The rupture may occur into the peritoneal cavity or into any of the surrounding structures and fistulous communications may be established with the pleural or pericardial cavities, or even with the exterior through the abdominal walls. Abscesses of the liver, spleen, or pancreas may result from perforation into these organs. In the healing of the ulcers scars are formed in the wall of the stomach. These have usually a rather characteristic stellate shape. In case of large ulcers extensive scars and considerable construction of portions of the walls of the stomach result. Hour-glass contraction of the organ, or pyloric stenosis, may follow, and secondary changes, such as gastric dilatation, may ensue. Carcinomatous transformation is a not infrequent result of long-standing ulceration." (Stengel's *Pathology.*)

6. *Operative treatment for inguinal hernia.* "When the hernia cannot be efficiently controlled by a truss, when it is irreducible, and when there has been a threatened or actual strangulation, this is the most satisfactory method of treatment. In congenital cases and in cases complicated by imperfect descent of the testis, also, operation is indicated. Operation is also performed in young men who intend entering one of the public services, or who are going abroad, where they may be out of reach of surgical assistance; and in cases in which, from the nature of the patient's occupation and habits, the use of a truss is liable to be interfered with. In many cases the choice between the wearing of a truss and operation may be left to the patient. Cases unsuited for operation include those in which the hernia is of such enormous size that the abdomen is unlikely to be able to accommodate the protruded viscera, and those in which the abdominal walls are flaccid and bulging, and in which the conditions that have led to the formation of the hernia are likely to continue, for example persistent coughing, or straining on micturition." (Thomson and Miles' *Surgery.*)

*Structures divided in operation for inguinal hernia:* Skin, fascia, aponeurosis of external oblique, internal oblique muscle, transversalis muscle, sac (peritoneum); arteries, veins, lymphatics, and nerves.

7. EMPYEMA. *Pathology:* The organisms causing it are pneumococci, streptococci, staphylococci, tubercle bacilli, *Bacillus coli*, and actinomycosis.

The physical signs are those of fluid in the pleural cavity; that side does not move well, the percussion note is dull, there is absence of breath sounds, vocal fremitus and resonance are diminished. Left alone, an empyema may burst through an intercostal space, usually the fifth. The lung is collapsed in extent according to the amount of pus. The pleura, at first covered with lymph, soon becomes covered with layers of granulation tissue, the deeper part of which is converted into fibrocicatricial tissue, and the lung itself also undergoes some fibroid change. If the pus is let out early the lung and pleura soon expand, but if allowed to go on the infiltration of the lung and the density of the scar tissue covering it hinder expansion. Nature attempts to remedy this in various ways. (1) The other lung expands and pushes the heart over to the opposite side; (2) the chest wall falls in, the intercostal spaces are obliterated, and the spine is curved, with its concavity toward that side; (3) the abdominal viscera are pushed up; and (4) exuberant granulations form on the pleura. If a cavity still remains an operation is necessary.
